cutting modalities difficult. Success following wire-mounted cold-knife incision was 60.5% in the largest patient series at a mean follow-up of almost 39 months [28]. However, other experiences with this modality are quite limited in the literature. Electrocautery and holmium laser incisions were associated with similar mean success rates of 69% and 72%, respectively, though mean follow-up in the laser groups was shorter (17.9 vs 31 months) [3, 5, 23, 24, 30, 38, 58]. Both techniques allow for precise incision under direct visualization and hemostatic control with instrumentation familiar to most urologists. The electroincision group was mainly composed of Acucise treatments, though one study utilized a 7F electric papillotome [57]. The mean patency rates following electroincision (48%) were lower as compared to the other endoureterotomy modalities, but higher than balloon dilation alone [13, 23, 53–57]. As noted with primary balloon dilation, all studies utilized stents at the conclusion of the procedure. However, there was no consensus as to stent size (6–22F) and duration of stenting (1.5–22 weeks), though a 6-week period was commonly cited. Predictors of postoperative success included shorter stricture length (<1 cm) and right-sided stricture, though this was not uniform in all studies [3, 5, 13, 23, 24, 26, 28, 30, 38, 51–58]. Patients with poor ipsilateral renal function (<25% of total renal function) were unlikely to maintain patency after endoureterotomy [13].

Improvements in long-term patency rates following endoureterotomy may be contingent on a better understanding of the healing process of the ureter following incision. Unlike during open revision of the anastomosis, healing of the tissue occurs through secondary intention. Animal studies since the seminal reports by Davis note a predominance of myofibroblasts during the initial healing period, suggesting that healing may, in part, occur through wound contraction. Thus, the ureteral stent may serve as a mold during healing rather than as a scaffold for cell regeneration [59]. This finding may explain some reports that larger stent sizes were associated with improved outcomes [13, 60]. Increased collagen deposition resulting in fibrosis and scarring has also been observed in histologic specimens of failed ureteral stricture repairs [61]. Local injection of adjunctive triamcinolone may block collagen formation and subsequent scarring [25]. Though reported use during endoureterotomy is limited, steroid injection following stricture incision has been beneficial in select series [13, 26]. Ureteral stent duration may also affect healing. As noted in the included citations, a 6-week stent period was most commonly utilized, likely based on the findings of Davis. However, some porcine studies have noted more favorable histologic changes with a shorter stent duration, particularly for strictures greater than 2 cm [62]. Continued research is necessary to determine the optimal healing parameters following ureteral endoureterotomy.

Ureteral stenting

Chronic indwelling ureteral stent placement may be considered in patients with significant comorbidities or more likely in patients with a limited life-expectancy secondary to their primary disease. Review of 11 publications detailing 86 procedures utilizing various ureteral stents for primary ureteroenteric stricture treatment noted a success rate of 16.7–100% (mean 81%) at a mean follow-up of 6–22.4 months (Table 45.3) [12, 63–72]. Unlike temporary stent placement after balloon dilation or endoureterotomy, use of synthetic stents for primary treatment is not widely reported. One review of 20 procedures noted only a 45% long-term patency rate at a mean follow-up of 26 months. Even in successful patients, ongoing periodic stent exchange was required [12]. Repeated antegrade or retrograde insertion of the stent, particularly in patients with ileal conduits, can be difficult and may require novel techniques to aid with insertion [73]. The literature regarding use of the relatively new metallic double-pigtail stent for ureteroenteric strictures is also limited. In six cases of ureteroenteric stricture, placement of a metallic double-pigtail stent only had a 50% prolonged success as compared to 100% patency in 25 procedures for malignant obstruction [63]. The reported patency rates (mean 89.6%) for the short, permanent metal stents initially appeared more promising, but reports are characterized by small sample sizes and short follow-up (mean 12 months) [64–72]. In the largest series of 24 procedures, primary patency at 4 years was only 22.7% but increased to 56.7% after secondary interventions [64].

Complications

The reported complications following endoscopic management of ureteroenteric strictures are generally related to the surrounding anatomy and comorbid diseases. Similar to all urologic procedures, UTIs, and potential sepsis can occur following endoscopic manipulation, particularly in this high-risk population with colonized urinary diversions. Specific surgical complications directly associated with balloon dilation are few. Following endoureterotomy, in a series of 30 treatments, six major complications were reported, including one blood transfusion, three febrile UTIs, one sepsis, and one lacerated common iliac artery [13]. A series of 14 electrocautery procedures noted one ureteroenteric fistula that healed following prolonged stent placement [26]. Vascular injuries are a particular concern with electroincision endoureterotomy. In a multicenter trial of Acucise incisions, the authors noted common iliac artery

injuries in 4% of patients and cautioned against the use of the device in ureteroenteric strictures [56].

In the normal anatomy, the distal ureteral segment is supplied laterally by branches of the inferior vesical artery. More cranially, the internal and common iliac arteries cross the ureter posteriorly. Following urinary diversion and reimplantation, the ureteral anatomy may be more distorted. Incisions anteriorly (12 o'clock) in the supine or dorsal lithotomy positions and posteriorly (6 o'clock) in the prone position are generally considered to be safe [27]. Further evaluation of adjacent vessels or bowel on preoperative CT imaging can be useful for surgical planning. Additionally, direct ureteroscopic visualization prior to visual or fluoroscopic incision or endoluminal ultrasonography may be used to detect arterial pulsations [35, 57].

The problems reported following prolonged ureteral stent placement are generally not vascular related (Table 45.3). *In situ* stents, particularly synthetic stents, are at risk for encrustation and obstruction with possible development of worsening renal function, urosepsis, and death [12, 74]. Even more common, chronic indwelling stents have been associated with fairly significant irritative voiding symptoms and discomfort in some patients [75]. Stent migration may also occur [12]. One series of 10 ureteroenteric strictures managed with metallic double-pigtail stents observed distal migration in 90% cases at a mean of 21 days (3–60) after placement. The authors hypothesized that the heavier weight of the metallic stent in combination with the increased motility of the bowel segment may have contributed to the occurrences [34]. However, this observation was not observed in other reports [63, 76]. Urothelial hyperplasia, stent migration, and encrustation are reported complications with the short, permanent metal stents [33]. Early hyperplasia is thought to be reactive secondary to the mechanical trauma exerted by the stent on the ureteral wall [64]. While endoscopy studies suggest that the hyperplasia may regress 4–6 weeks after stent insertion [66], urothelial ingrowth of the stent can result in complete occlusion of the ureteral lumen [77]. Secondary procedures within the metal stent, including balloon dilation, placement of a double-J stent or lithotripsy may be attempted as a salvage maneuver [63, 64, 69].

Postoperative follow-up

Given the variable reported success rates in the first few years following endoscopic management of ureteroenteric strictures, a regimented postintervention surveillance imaging protocol is necessary [24, 28, 38]. Both diagnostic imaging as well as functional renal studies should be obtained periodically to document lack of ureteral obstruction as well as to prevent loss of renal function [23]. We typically obtain excretory urography

Figure 45.4 Excretory urography at 3 months after balloon dilation and holmium laser endoureterotomy reveals resolution of left ureteroenteric stricture.

or renal scintigraphy at 3 months postoperatively (Figure 45.4). Clinical evaluation and renal scintigraphy are performed at 3–6-month intervals for the first 2–3 years. Additionally, renal ultrasonography and CT imaging are alternatively performed at these follow-up visits. The imaging modalities are spaced out further after the initial 2–3-year period. Repeated functional imaging, such as renal scintigraphy, excretory urography, antegrade nephrostography or loopography/neobladder cystography, are obtained if recurrence is suspected. Failures may be managed by a repeated or alternative endoscopic technique or treated with open revision.

Conclusions

The management of ureteroenteric strictures remains a challenging treatment dilemma. A variety of minimally invasive options is available due to advances in endoscopic instruments and these offer faster patient recovery. However, long-term success rates are less robust as compared to open surgical revision, and patients who fail endoscopic treatment may be at risk for slightly lower success rates and increased morbidity during later open surgery. Results following primary balloon dilation of ureteroenteric strictures have been disappointing. Endoureterotomy, regardless of the specific

cutting modality, is the endoscopic procedure of choice for ureteroenteric strictures. Patients with shorter (<1 cm), right-sided strictures and preserved renal function may be more likely to have favorable long-term patency, though a clear determination of predictors for success is not possible. Newer material or designed ureteral stents may have utility in select patients, though complications of tissue ingrowth and obstruction are problematic. Further clinical trials involving use of adjunct therapy, such as steroid injection, as well as continued understanding of the causation and post-treatment healing process of the strictured ureter may aid in improving long-term outcomes.

CHAPTER 46

Ureteroscopy: Ureteral Stents and Postoperative Care

Ben H. Chew & Ryan F. Paterson
Department of Urologic Sciences, University of British Columbia, Vancouver, BC, Canada

Introduction

Ureteroscopy (URS) is commonly used to treat urolithiasis and has become a standard endoscopic technique, replacing open stone surgery. This chapter will discuss analgesia and other medications utilized in the postoperative period. The use of ureteral stents and new and future technologies will also be discussed. Finally, the use of postoperative imaging following URS will be examined.

Ureteroscopy: outpatient versus inpatient management

The overwhelming majority of patients undergoing flexible or semi-rigid URS and intracorporeal lithotripsy are treated on an outpatient basis. Common indications for unplanned admission post procedure include flank or bladder pain not manageable with oral analgesics, fever, urinary retention, or significant hematuria. In addition, management of the uncommon procedural complications of ureteral perforation or avulsion account for a small percentage of admissions. In common with other planned outpatient procedures, late procedure start times and social circumstances precluding early discharge may result in overnight admission [1]. Table 46.1 lists techniques to increase the likelihood of maintaining URS as an outpatient procedure.

Emergency admission for renal colic with subsequent treatment with emergent URS can increase the likelihood of ongoing hospital stay post procedure [1]. Many urologists will have anecdotal experience of easier discharge post procedure when a patient who presents emergently with renal colic undergoes prompt URS treatment.

Prescriptions

Following any surgery, physicians typically prescribe medications for the postoperative period consisting of an antibiotic and/or analgesic. Following URS, there are many types of analgesics that can be prescribed and there is very little evidence regarding antibiotics in the postoperative period. In addition, two other types of medications can be prescribed to patients with urolithiasis. In the case of uric acid stones, patients may be prescribed a urinary alkalinizing agent to dissolve any remaining fragments. The second type is alpha-antagonists, which have been utilized to facilitate passage of fragments by relaxing ureteral smooth muscle [2–4] and to help alleviate postoperative ureteral stent symptoms [5–8].

Antibiotics

Patients are often prescribed antibiotics following surgery to prevent infection. The decision on whether to prescribe antibiotics should balance the risk of infection with the risk of adverse effects of antibiotics and the induction of antibiotic-resistant bacterial strains. In cases where the risk of infection is high, the risk of complications such as *Clostridium difficile* colitis justifies the

Smith's Textbook of Endourology, Third Edition. Edited by Arthur D. Smith, Gopal H. Badlani, Glenn M. Preminger, Louis R. Kavoussi.

Table 46.1 Technique to increase likelihood of outpatient ureteroscopy (URS).

Thorough discussion with patient and family preoperatively regarding post-URS clinical course and expectations
Operative start time during morning or early afternoon
Prompt surgical intervention in patients presenting emergently with renal colic
Dose of nonsteroidal anti-inflammatory, such as ketorolac, at completion of procedure
Bladder drainage at completion of procedure
Avoidance of routine ureteral stenting for uncomplicated URS
Appropriate stent length and diameter
Consideration of anticholinergic medications for stent-related bladder spasms
Consideration of alpha-blocker medication for stent discomfort

use of antibiotics. In cases where there is a low risk of infection, then the utility of postoperative antibiotic prophylaxis becomes less clear.

There is good evidence to give antibiotics at the time of surgery. A randomized trial of 113 patients were administered either levofloxacin 250 mg po 60 min prior to URS or no antibiotics [9]. The rate of bacteriuria in the control group was 12.5% compared to 1.8% in those receiving levofloxacin. The study did not examine the use of antibiotics in the postoperative period.

The American Urological Association guidelines recommend preoperative antibiotic prophylaxis in all patients undergoing URS with either a fluoroquinolone or trimethoprim (or alternatively with an aminoglycoside, penicillin, amoxicillin/clavulanate, or cephalosporin) for less than 24 h duration. Oral ciprofloxacin was shown to be equivalent to intravenous cefazolin, with a 9.1% infection rate in 77 patients undergoing urologic procedures (42 of these were URS) [10].

As mentioned above, there is no guideline or strong evidence in the literature for using antibiotic prophylaxis in the postoperative period.

Analgesics

Analgesics for renal colic and passage of fragments

The options for treating postoperative pain range from the commonly used analgesics, which target pain at the central nervous system, to medications that target specific receptors in the urothelium. The literature lacks suggestions for analgesics specifically after URS, but the passage of fragments after intracorporeal lithotripsy can be accompanied with pain very similar to that found in renal colic.

Alpha-antagonists for stone expulsion

Alpha-antagonists inhibit smooth muscle contraction and have been used extensively in the treatment of benign prostatic hyperplasia. In the endourologic world, they have found two further purposes: as medical therapy to facilitate stone expulsion and to relieve ureteral stent symptoms. The theory underlying these observations is relaxation of ureteral smooth muscle to allow ureteral stones to pass, and in the case of stents, to prevent ureteral spasm. This is done by inhibiting selective alpha(1)-adrenergic receptors and reducing ureteral contractility [11, 12].

Medical expulsive therapy has been found to increase the stone passage rate as well as hasten the time to stone passage, and reduce pain, narcotic requirement, and hospitalizations for renal colic [13, 14]. A meta-analysis evaluating 693 pooled patients found a greater likelihood, compared to placebo, of stone passage when they were given an alpha-blocker [risk ratio (RR) 1.54, 95% CI 1.29–1.85] or calcium channel blocker with steroids (RR 1.90 95% CI 1.51–2.40) [3]. The number needed to treat in this analysis was only 4, indicating that this is a worthwhile and effective treatment for ureteral stones. Some studies have produced an even higher rate of stone expulsion (RR 2.93, 95% CI 1.15–7.45) in patients administered tamsulosin [15].

Most studies have evaluated stones in the distal ureter, but what about proximal ureteral stones? A study evaluating stone passage rate in patients administered placebo versus tamsulosin also found an increased stone passage rate, as well as quicker stone passage time in those given tamsulosin with proximal ureteral stones [16]. Although the drug helped with spontaneous stone passage (35.7% vs 30%, $P = .04$), this effect was more profound in stones smaller than 5 mm (71.4% vs 50%, $P < .001$). Stones between 5 and 10 mm tended to migrate into the distal ureter more readily in those patients given the alpha-blocker (39.3% vs 18.7%). It would appear that alpha-antagonists also help spontaneous stone passage of proximal ureteral stones, and in the case of stones larger than 5 mm, help them migrate into the distal ureter where rigid URS is more easily performed.

Are all alpha-blockers equally effective? A randomized placebo controlled trial evaluating tamsulosin, terazosin, or doxazosin found equal rates of stone passage among all medications [17]. Different alpha-blockers, including the alpha (1A) selective antagonist, silodosin, and the alpha (1D) selective antagonist, naftopidil, have also been shown to inhibit ureteral contrac-

tility and reduce ureteral pressure in a dog model, and may be useful in expulsion of ureteral stones [18]. Naftopidil has been used clinically for stone expulsion with positive results, yielding a spontaneous stone passage rate of 90% versus 27% in controls for an increased probability of stone expulsion of 5.26 (95% CI 2.30–12.02) [19].

Prescribing alpha-antagonists may help facilitate passage of stone fragments following URS.

Analgesics for stent-related pain

Phenazopyridine and oxybutynin have been administered orally in an attempt to relieve stent-related symptoms. A trial involving 60 patients randomized to phenazopyridine, oxybutynin, or placebo recorded the following measures: narcotic use, flank pain, suprapubic pain, urinary frequency, urgency, dysuria, and hematuria [20]. There was a trend, although statistically insignificant due to the small group numbers, for a reduction in narcotic usage in the oxybutynin group. Phenazopyridine significantly reduced the amount of hematuria patients had on postoperative day 1 compared to placebo. Perhaps a larger study would discern if either of these medications would be helpful in relieving stent symptoms.

Alpha-blockers

Patients randomized to alfuzosin following URS and stent insertion had significantly less narcotic use, less overall pain in the back and groin area, less flank pain during urination and less urinary frequency compared to patients given placebo [21]. Tamsulosin also produced similar significant results in other placebo-controlled prospective trials of patients undergoing ureteral stent placement following URS [5, 8, 22]. It would appear that alpha-blocker administration post ureteral stent insertion is an excellent way to prevent and relieve symptoms.

Botulinum toxin A

It is unknown exactly from where stent symptoms originate. There is evidence that the junction of the ureter and bladder play a role. One trial randomized patients who had a ureteral stent post URS to three injections of botulinum toxin A into the bladder around the ureteral orifice or no injection [23]. Stented patients with botulinum toxin A experienced significantly less pain than controls and required less narcotic usage. This lends evidence to the theory that detrusor muscle spasm around the intramural ureter is a cause of ureteral stent pain. Most interestingly, the stent used in this study was a multilength ureteral stent [23]. There is a belief that more significant material in the bladder leads to more significant symptoms, but there are no randomized clinical data to support this anecdotal belief. The future and feasibility of delivering botulinum toxin A to patients with ureteral stents cannot be foreseen, but there is good evidence that it helps relieve stent symptoms.

To stent or not to stent?

The decision must be made at the end of each URS on whether or not a ureteral stent should be placed. The absolute indications to leave a ureteral stent are listed in Table 46.2 [24]. There is good evidence from randomized clinical trials suggesting that patients without ureteral stents fare better than those who receive a ureteral stent [1, 25–28]. Few unstented patients post URS require surgical intervention for ureteral obstruction, with the majority managed by improved pain control. In addition, the vast majority of patients treated on a "stentless" basis have no obvious preprocedure predictor of subsequent flank pain or obstruction. Supporting the role of postprocedure ureteral stenting is the study by Borboroglu *et al*. in which a risk for admission for flank pain post URS of 7.4% was reported in the unstented group versus a 0% readmission rate in the stented group [29]. However, the overall cohort of unstented patients had substantially less flank pain. Although the avoidance of a postprocedure ureteral stricture is commonly encountered in the literature as a justification for ureteral stenting, the meta-analysis of randomized controlled trials by Nabi *et al*. indicates no difference in stricture rate between those stented and not stented [30].

While some studies have shown fewer symptoms and less pain in those patients without a stent, a meta-analysis found a trend towards fewer urologic

Table 46.2 Indications for ureteral stenting post ureteroscopy (URS) (from Chew and Denstedt [24] with permission).

Ureteral perforation intraoperatively
Ureteral dilation greater than 10F (either coaxial or balloon dilator)
Significant ureteral edema due to stone (e.g. impacted stone)
Failure to advance the ureteroscope due to a narrow ureter or ureteral orifice and in preparation for a subsequent URS after 7 days
Infected urinary system with an obstructing system
Large stone burden with many fragments still to pass
Solitary kidney

complications in patients who received a stent following URS [31]. Some of the trials included in the analysis found no difference in complication rates between stented and unstented patients, but there was an overall 4.5% reduction in rate of complications in those patients who underwent placement of a stent following URS (95% CI 1.8–7.3%, $P = .001$). When a more stringent random effects model was applied, however, this difference was not statistically significant (4.1% risk difference, 95% CI 1.8–10.1%, $P = .175$). At present in the literature, there is no significant difference in outcomes between patients who receive a ureteral stent compared to those who do not receive a ureteral stent following URS.

Which stent is most comfortable?

Once a decision to place a stent is made, the question becomes which stent to use. This question is often asked, but there are no conclusive data as to which commercially available stent is the most comfortable for patients. There are a variety of factors that are taken into consideration, including the softness (durometer) of the stent, its design, and its size (both length and diameter).

Intuitively, softer stents would be expected to be more comfortable than harder stents; however, randomized trials have shown no difference between soft and hard stents in terms of urinary symptoms, pain, time away from work, or sexual dysfunction utilizing the Ureteral Stent Symptom Questionnaire (USSQ) [32], the only validated tool for evaluating ureteral stent symptoms [33, 34]. In one trial, patients randomized to a "stiffer" stent (>64A; Percuflex® stent; Boston Scientific, Natick, MA, USA) were compared to patients who received a softer stent (<64A; Contour™ stent; Boston Scientific;) [33]. No differences between the groups were seen at 1 and 4 weeks in terms of urinary symptoms, overall body pain, work performance, or general health index. Lennon *et al*. randomized patients to firm polyurethane stents or a softer Sof-Flex™ stent (Cook Medical, Bloomington, IN, USA) [34]. Patients with firmer stents had a higher rate of dysuria, and renal and suprapubic pain; however, there was no significant difference in the degree of bladder inflammation, stent encrustation, urgency, frequency, nocturia, or hematuria. The only shortcoming of this study is that patients were not evaluated with a validated stent symptom questionnaire, the USSQ.

More recently, Lingeman *et al*. and the Comfort Study Team utilized the USSQ to assess whether patient comfort was best with a short loop tail stent, a long loop tail stent, a Percuflex Plus stent, or a Polaris stent (Boston Scientific) [35]. All kidney curls were identically composed of a 6F pigtail curl and the Percuflex Plus stent consists of the same material and coil in the bladder end. The distal ends differed in the other three stents: the short loop tail stent consisted of two loops that were 5 cm long and 3F in diameter compared to the long loop tail stents which also had two loops but these were 8 cm long and 3F in diameter. The Polaris stent is a dual durometer stent with a stiffer renal curl to prevent migration, but a softer curl in the bladder in an attempt to decrease bladder irritation and symptoms. Two hundred and thirty six patients were randomized to receive one of the stents following uncomplicated URS and were administered the USSQ at baseline, 4 days after stent placement, and 5 days after stent removal. There were no statistically significant differences in pain scores between any of the stent groups. There was decreased use of narcotics in the first 1–3 days after stent placement in the short loop tail stents, but this was insignificant at the 4-day mark. Most notably, the USSQ may not have been administered at the correct time as all patients had the most severe discomfort symptoms on postoperative day 1. By day 4, when the USSQ was administered, all symptoms had subsided. Despite the fact that the authors developed their protocol to test the stents at day 4, there may have been a significant difference if it were measured at day 1. This finding supports the theory that stent symptoms occur from irritation of the trigone of the bladder. A softer material that also has less mass in the bladder may help alleviate ureteral stent-related symptoms.

Stent length relating to discomfort

Even though there are no clear data to support the use of one type of stent over another, there are good data that longer stents that protrude further into the bladder produce more symptoms. Choosing the correct length stent will significantly help reduce patient stent symptoms. Stents that cross the midline of the bladder result in significantly more dysuria, urgency, and irritative voiding symptoms than stents that do not cross the midline [36]. Long stents are associated with excess material in the bladder and, therefore, presumably with more bladder irritation, but do not result in excess stent length in the kidney [36]. Fluoroscopic studies of stented patients show that, with motion, the stent tends to bow in the mid and proximal ureter and the excess length slides in and out of the bladder at the ureterovesical junction, with relatively little movement in the kidney [37]. Flank pain was not affected by stent length, but there is good evidence that negative bladder symptoms are increased in patients with longer stents compared with those who are stented with a stent of the correct length.

How is the correct stent length chosen? This question has baffled many a urologist and many methods have been described, including measuring patient height, torso length, intravenous urography, and direct ureteral

measurement. One study found that direct intraoperative measurement of ureteral length was better than patient height at correlating with the correct length of stent [38]. Another study evaluated several anthropometric factors, including patient height, body mass index (BMI), and distances from the acromium process (shoulder) to the head of the ulna (wrist), olecranon process (elbow) to the head of the ulna, xiphoid process to the pubis, umbilicus to the pubis, and anterior iliac spine to the anterior iliac spine [39]. Ureteral length intraoperatively with a 5F ureteral catheter was measured and it was found that height, xiphoid process to pubis distance, and the shoulder to wrist distance all correlated with ureteric length. Ho *et al*. recommended a 22-cm stent for patients of 149.5–178.5 cm in height, but they did not study patients outside this height range [40]. To date, there is no standard accepted method of determining the most appropriate length of ureteral stent.

Drug-eluting ureteral stents

One of the newest technologies is to release drug to the immediate tissues surrounding the stent via a drug-eluting ureteral stent. Similar to drug-eluting coronary artery stents to help prevent arterial restenosis, a drug could be loaded into the bulk material of a stent or into the coating to elute over time. The advantage of local drug delivery is the high concentration of drug in the tissues surrounding the stent. To deliver similar high concentrations of drug to local tissues would require very high systemic levels, which would increase the risk of systemic side effects; with drug-eluting technology, the systemic levels are practically negligible, yet a high concentration of drug is delivered to the local area.

Drug-eluting ureteral stents have been used to tackle two problems: infection and stent symptoms. The first drug-eluting ureteral stent available on the market involved the use of the antimicrobial triclosan that is used in over 800 commercial products. It is not an antibiotic *per se*, but inhibits fatty acid synthesis which is necessary for building cell membranes. A triclosan-eluting ureteral stent (Triumph™ stent; Boston Scientific) was shown to be effective against common bacteria *in vitro* [41, 42] and against *Proteus mirabilis* in a rabbit model [43]. However, in patients who required a long-term stent, the triclosan-eluting ureteral stent did not reduce stent-related infections [44]. This stent has never been approved in the USA due to Federal Drug and Administration (FDA) fears that it may induce antibiotic-resistant organisms, although triclosan has never been shown to induce resistance.

In order to determine which drug would help with stent comfort, a randomized study assessed whether intravesical administration of oxybutynin, lidocaine, or ketorolac would improve stent symptoms compared to a saline control in patients who were stented immediately before shock-wave lithotripsy [45]. The nonsteroidal anti-inflammatory, ketorolac, was found to significantly reduce stent-related flank pain compared to controls and the other agents. A ketorolac-eluting ureteral stent (Lexington™; Boston Scientific) was developed to elute its medication over 90 days, with the majority of the drug released within the first 30 days. The safety and tissue levels of ketorolac was first tested in a porcine model of 92 animals either stented with a ketorolac-eluting ureteral stent or administered oral ketorolac as a control [46]. Plasma levels of ketorolac were approximately 11-fold lower in the animals that received a ketorolac-eluting stent compared to the control group that received oral ketorolac. The highest level of ketorolac in the ketorolac-eluting stent group was found in the ureteral tissue, the target area for this medication to reduce symptoms. This study highlights that a drug-eluting ureteral stent can be used to deliver high levels of drug to the local area while minimizing systemic levels and, therefore, reducing adverse effects.

A clinical trial randomized 276 patients to receive either a ketorolac-eluting ureteral stent (13% drug by weight) or a control nondrug-eluting ureteral stent following URS [47]. The primary end-point was to reduce the number of interventions, including unscheduled physician contact, early stent removal, or change in analgesic medications. The authors reported no difference in primary (9.0% ketorolac loaded vs 7.0% control, $P = .66$) or secondary (22.6% ketorolac loaded vs 25.2% control, $P = .67$) intervention rates. However, further analysis demonstrated that the mean pain pill count at day 3 was lower in the ketorolac-loaded stent group than in the control group ($P < .05$). In addition, a greater percentage of patients with ketorolac-loaded stents used no or limited pain medication compared to controls (32% vs 22%, $P = .057$). Age was found to play a role in stent discomfort with patients over 45 years old in both cohorts using less pain medication than their respective younger cohorts. In addition, in patients younger than 45 years, those with ketorolac-loaded stents used fewer pain pills on days 1–4 compared to those with control stents ($P < .05$). This study suggests a potential benefit of ketorolac but may have been underpowered to statistically confirm this trend. This was the first drug-eluting ureteral stent used clinically in an attempt to improve patient comfort.

In the future, drug-eluting ureteral stent technology will potentially be used not only to treat discomfort, but also infection, encrustation, or other urologic diseases such as prostatitis, interstitial cystitis, or upper tract transitional cell carcinoma.

Biodegradable ureteral stents

Ureteral stents typically require a secondary procedure for removal if a suture tether is not used. This can add cost, inconvenience, and discomfort for the patients. In addition, if a patient is lost to follow-up and if there is any miscommunication about the fact that the patient has a stent, this can lead to a "forgotten" stent potentially requiring several surgeries for removal or even loss of the renal unit [48–51]. There have been case reports of mortality stemming from forgotten ureteral stents [52]. Attempts to reduce retained stents have included a stent registry [53, 54]. A stent without a suture tether that does not require cystoscopic removal has also been developed using a high-powered magnet catheter that is inserted into the bladder to bind a steel bead attached to the distal end of the stent for removal [55]. This low-cost alternative to cystoscopy offers a safe "blind" removal of the ureteral stent in any type of setting under local anesthetic.

Perhaps the holy grail of preventing a retained stent is one that would degrade over time. The properties of an ideal biodegradable stent are that it must function to provide drainage like a plastic stent, be easy to deploy, be radio-opaque, maintain its integrity for at least a certain amount of time in order for ureteral edema, etc. to subside, but not overstay its welcome and take too long to degrade. Furthermore, it should be comfortable, biocompatible to surrounding tissues, and degrade in a fashion that does not obstruct the distal ureter.

Lingeman *et al*. performed a phase I clinical trial to evaluate the Temporary Ureteral Drainage Stent (TUDS; Boston Scientific) in 18 patients [56]. All stent material was extruded within 4 weeks with only one stent prematurely migrating into the bladder at day 1. A phase II trial of the TUDS stent evaluated 88 patients following URS and the stents were eliminated from the ureter at a median of 8 days and eliminated completely from the body at a median of 15 days [57]. By 30 days, 84% (74 of 88) of the stents had completely degraded. Unfortunately, in three patients, stent fragments remained at 3 months and these patients required surgical intervention for their removal. For the majority of patients (78.2%), the stent was effective at providing upper tract drainage for at least 48 h postoperatively, the targeted time to define success. Due to the manufacturer's concerns about retained fragments, the TUDS stent is no longer commercially available.

A more recent degradable stent composed of L-lactide, glycolide, and copolyester components similar to those found in absorbable sutures has been developed and tested in a porcine model (UripreneTM; Poly-Med Inc, Greenville, SC, USA) [58]. It has been developed to degrade within 2–3 weeks with all stents being completely eliminated from the body by week 4 in a porcine model [59]. The stent was biocompatible on histology and did not result in any hydronephrosis in comparison to the control biostable stents. Drainage was also superior to that with control stents, as seen on weekly intravenous pyelograms (IVPs). The safety of this stent has been tested and proven in an animal model of ureteral stenting. Human trials will determine its true degradation time and if there is any improvement in comfort. Hopefully, the development of biodegradable stents will aid in reducing stent symptoms and infection, and avoid the forgotten stent syndrome.

Postoperative imaging following ureteroscopy

Routine imaging postoperatively remains controversial despite over a decade of studies reported in the era of small-diameter, semi-rigid and flexible ureteroscopes. Multiple authors, in the setting of either a randomized controlled trial of stented versus unstented URS or a retrospective case series, have demonstrated a low risk of post-URS obstruction[1, 25, 27, 29, 60–77] (Table 46.3). Given the high stone-free rate for URS of upper tract calculi, the major indication for postprocedure imaging is the detection of a ureteral stricture, with a risk in uncomplicated cases of less than 5%. Predisposing factors for ureteral stricture post URS include preoperative factors such as chronic stone impaction, reduced renal function, coexistent ureteral stricture on the treated side, and complete ureteral obstruction [68, 77, 78]. In addition, intraoperative factors such as significant ureteral edema, ureteral trauma, or ureteral perforation are established risk factors for ureteral stricture and mandate close long-term radiologic follow-up [68, 78]. Indeed, the retrospective case series of Roberts *et al*. reported a 24% incidence of ureteral stricture in patients with chronic ureteral stone impaction of greater than 2 months [78]. However, previous iatrogenic ureteral perforation from previous stone manipulation was encountered in the majority of stricture cases. Regardless, the more contemporary series of Beiko *et al*. reported that all four cases of ureteral stricture post URS occurred in patients with identifiable preoperative risk factors [68].

Adiyat *et al*. retrospectively compared the incidence of ureteral stricture between a high-risk group of complicated URS cases (n = 56) and a cohort of uncomplicated URS patients undergoing routine stone surveillance imaging (n = 158) [77] (Table 46.3). In common with other authors, cases of complicated URS, consisting of those with encountered impacted stone, need for ureteral balloon dilation, or ureteral perforation, demonstrated a substantial risk of ureteral stricture of 5.3%. In contrast, long-term radiologic surveillance in the uncomplicated URS group (mean follow-up of 10.2 months) revealed no ureteral strictures. The predisposition of a

Table 46.3 Ureteroscopy (URS): Follow-up imaging.

Numbers of patients, where reported, consist of patients with upper tract urolithiasis undergoing URS intervention.
R, semi-rigid ureteroscope; F, flexible ureteroscope; U/S, ultrasound; CT, computed tomography; NCCT, noncontrast CT; IVP, intravenous pyelogram; KUP, kidneys, ureters, bladder.

ureteral stricture from ureteral balloon dilation remains controversial, with some authors suggesting this is a risk factor [68, 77], while others do not [1]. Again, further evidence is needed to support selective imaging limited to patients with known risk factors for postoperative ureteral stricture development.

Multiple authors advocating limited radiologic evaluation in the early post-URS period have based this recommendation on the presence or absence of pain as an indication for imaging [72]. The majority of studies assessing the etiology of pain after URS demonstrate a substantially greater likelihood of a retained stone fragment rather than a stricture being responsible [65, 77]. Bugg *et al*., as advocates of limited post-URS imaging, reviewed the chance of postoperative obstruction when preoperative obstruction and postoperative pain are combined [65]. The authors reported that patients with preoperative obstruction and postoperative pain had a 67% chance of having residual fragments and a 50% chance of residual obstruction. In contrast, 96% of patients without preoperative obstruction and no postoperative pain had no persistent obstruction or residual fragments. However, the risk of missing silent obstruction remains, as 25% of asymptomatic patients had residual stone fragments or obstruction. The authors suggest that the ready availability of renal ultrasound could substitute for IVP or CT in the detection of obstruction for physicians not comfortable with avoidance of routine imaging post URS.

The correlation of pain with post-URS ureteral obstruction has been questioned by Wiezer *et al*. who caution urologists regarding the risk of silent hydronephrosis [64]. In this retrospective case series from the Duke University group, the absence of pain was noted in seven patients who presented postoperatively with silent hydronephrosis (of a total of 241 patients). This translates into a 3% risk of renal functional impairment in patients undergoing URS if relying only on symptoms to prompt imaging. In common with Wiezer *et al*., Manger *et al*., in a retrospective case series of 289 patients with available post-URS sonography, report that 27 (9.3%) had sonographic evidence of hydronephrosis [74]. Of these 27 patients with hydronephrosis, 14 were asymptomatic and 13 reported ipsilateral flank pain. From this series, the risk of silent obstruction is significant (4.8%), with the authors calculating the number needed to diagnose one case of hydronephrosis as 18 asymptomatic patients post URS. Further, the negative and positive predictive values of ipsilateral flank pain for hydronephrosis were 94% and 35%, respectively. In conflict with this large percentage of patients with post-URS hydronephrosis (providing evidence for routine post-URS imaging) is the small number of patients in this series with asymptomatic hydronephrosis who eventually required surgical intervention.

The majority of studies assessing imaging post URS have relied on IVP or CT scans to rule out obstruction. In contrast, Manger *et al*. demonstrated the value of renal ultrasound post URS as a screening study [74]. Given the increasing recommendations to limit medical radiation exposure in patients combined with the ready availability of sonography, the authors recommend renal ultrasound as the imaging study of choice post URS in asymptomatic patients to rule out obstruction [79, 80].

Conclusions

URS remains an effective outpatient tool in the treatment of stones. There is good evidence for preoperative antibiotic prophylaxis, but no evidence for antibiotics following URS. Postoperative use of ureteral stents is not supported for every routine, uncomplicated URS. If a stent is to be left, however, the proper length stent should be inserted to reduce stent symptoms. Ketorolac, oxybutynin, or an alpha-antagonist may help reduce stent-related symptoms. Drug-eluting ureteral stents may be used in the future to reduce stent symptoms. Botulinum toxin A may be a future drug to be eluted from stents to reduce symptoms. Alpha-antagonists may also be prescribed postoperatively in an attempt to facilitate spontaneous expulsion of stone fragments. Postoperative imaging should include ultrasonography to evaluate for hydronephrosis and obstruction regardless of symptoms.

CHAPTER 47
Ureteroscopy Complications

Petrisor Geavlete
Department of Urology, Saint John Emergency Clinical Hospital, Bucharest, Romania

Introduction

Ureteroscopy (URS) has become a major technique for the diagnosis and treatment of lesions involving both the ureter and the intrarenal collecting systems. Both the technique and instrumentation of URS have evolved dramatically and its indications have expanded in a proportional manner [1, 2].

The development of smaller semi-rigid or flexible ureteroscopes and of modern energy sources has significantly decreased URS-related incidents and complications [3, 4]. The decline in the incidence of ureteral injury has been particularly significant. The intraoperative complication rate, most notably represented by the ureteral perforation rate, has decreased to less than 5%, and long-term complications, such as stricture formation, occur with an incidence of 2% or less [1, 5]. However, despite significant technologic advances, surgical misadventures still occur, some of which have lasting consequences [4–6]. Careful attention to instrument selection and surgical technique are critical for reducing untoward events related to URS. Ideally, any complications associated with URS should be related to the underlying pathology rather than to treatment.

Classification

Although a formal classification system for secondary URS lesions has not yet been established, most authors define them by severity and time to occurrence. Complications can be divided into intraoperative, and early or late postoperative, and then each of these categories can be further subdivided into major and minor complications.

Most URS complications are minor, do not require specific measures or can be solved endoscopically [6]. The major complications, even though of reduced incidence (<1%) [5], may be serious and can cause significant morbidity.

Although most complications occur intraoperatively, their sequelae often appear in the early or late postoperative period. However, certain events that occur during URS will require supplementary maneuvers in order to complete the procedure; these are usually classified as intraoperative incidents. A few complications arise primarily postoperatively, such as infection or urinary retention [5].

Predisposing factors

There have been several studies of the factors that may be associated with an increased risk of complications. In a study of 322 cases, Schuster *et al*. noted a significant association between postoperative complications and kidney stones, operative time, and decreased surgeon experience, as well as a trend toward significance for the type of ureteroscope used [7]. In multivariate logistic regression models, ureteral perforation remained highly correlated with the operative time when controlling for the other factors. More recently, Abdelrahim *et al*. reported that symptoms present for more than 3 months, a negative history of schistosomiasis, a positive history

Smith's Textbook of Endourology, Third Edition. Edited by Arthur D. Smith, Gopal H. Badlani, Glenn M. Preminger, Louis R. Kavoussi.

of ureteral surgery, stones above the ischial spines, stones of 5 mm in width, a dilated proximal ureter, kidneys that failed to excrete contrast, and involvement of a junior urologist were factors associated with a statistically significant higher incidence of intraoperative complications [8]. Similarly, El-Nahas *et al*. demonstrated that significant factors for unfavorable results were proximal ureteral stones, URS performed by surgeons other than experienced endourologists, stone impaction, and stone width (relative risks 4, 2.5, 1.8, and 1.2, respectively) [9].

In their evaluation of 105 URS holmium:YAG lithotripsy procedures, Leijte *et al*. demonstrated a complication rate of 12.4% [4]. They concluded that greater surgeon experience is significantly correlated to higher success and lower complication rates in URS holmium:YAG laser lithotripsy. Sex, stone location, stone size, and age did not significantly influence complication or success rates.

T Complication rates remain low even in select cases, such as children or pregnant women [1]. The risk of major complications to the mother and fetus for urologists who are experienced with URS procedures should be less than 2% [10].

Intraoperative incidents

Difficulties of ureteral access

Technologic advances in ureteroscope design have facilitated access to the upper urinary tract. However, difficulties in ureteral orifice and intramural ureter negotiation or ureteroscope progression may still be encountered. Access failure prohibits URS and represents a significant incident. Trauma to the ureteral orifice or intramural mucosa can increase the difficulty of subsequent URS. This incident occurs in 1.6% of cases [7] and may be associated with musculoskeletal abnormality and contractures, narrowing of the ureter secondary to stricture or extrinsic compression, obstruction caused by edema or impacted stone, and iatrogenic ureteral lesions [11].

The ureteral orifice may be difficult to visualize or catheterize in men with a large prostatic median lobe or in women with cystocele. Several options have been described to facilitate the guidewire insertion, such as placing the guidewire over a ureteral catheter, emptying the bladder, using a flexible cystoscope and hydrophilic guidewires, or URS placement of the guide [12]. In some cases, even if the ureteral orifice can be visualized and a guidewire placed, the negotiation of the orifice with the semi-rigid ureteroscope may be difficult to accomplish. Attempting to straighten the ureter with a super-stiff wire or by using a flexible ureteroscope may be helpful. In selected cases, the URS approach through the ureteral orifice may be helped by performing intramural ureter dilation. Balloon dilation permits faster, less forceful access through the ureteral orifice into the ureter and upper tract, which is particularly important if multiple passes of the ureteroscope are necessary [13]. Although routine ureteral dilation was necessary for URS using the early larger (>10F) ureteroscopes, this principle has been questioned with the advent of smaller caliber rigid and flexible ureteroscopes [14]. Facilitating the ureteral orifice approach by using two guidewires represents a simple, efficient, and inexpensive way of avoiding ureteral orifice dilation.

The ureteral access sheath allows easier introduction of the ureteroscope in cases that require multiple passages. Experimental studies have confirmed secondary ureteral ischemia, although no long-term clinical sequelae, such as ureteral strictures, have been attributed to it [15].

Previously reimplanted, ectopic, and duplicated ureters may be difficult to access as well. Pelvic or retroperitoneal surgery or radiation therapy can fix the ureter in the deep pelvis. This situation significantly increases the risk of perforation, particularly when a rigid instrument is used. Likewise, guidewire or ureteroscope advancement may be difficult in cases of ureteral stricture or tortuosity. These conditions are most frequently subsequent to surgical interventions or related to a physiologic narrowing of the lumen. In these cases, using a hydrophilic guide may help the maneuver. Difficulties in advancing a guidewire may be overcome by inserting it under direct visual control, without trying to push it through the obstacle.

Another reason for access failure is the inability to overpass a calculus with the guidewire. This can be negotiated by instillation of intraureteral lidocaine jelly [11]. Usually, in such situations, a ureteral catheter may be introduced up to 1.5 cm below the stone. A hydrophilic guidewire is then inserted along this catheter, which can easily pass by the calculi. Afterwards, the catheter is pushed above the obstacle and the hydrophilic guidewire is replaced with a regular one. If this maneuver fails, the ureteroscope may be advanced up to the stone, thus advancing the wire under visual control.

In case of failure, the guidewire may be placed under antegrade URS control. If calculi cannot be overpassed by the guide when placed antegradely or retrogradely, a percutaneous nephrostomy followed by resumption of retrograde maneuvers after 2 weeks is the most recommended option.

Correct patient selection, as well as the use of appropriate technique and devices, can reduce the risk of this incident. Small semi-rigid or flexible ureteroscopes facilitate access to the upper urinary tract. Percutaneous nephrolithotomy and extracorporeal shock-wave

lithotripsy (ERCP) remain valid options in cases of a failed URS approach.

Equipment failure

Although the introduction of smaller ureteroscopes and miniature accessory instruments has increased the maneuverability of URS, these instruments are fragile, displaying a high prevalence of malfunction (see Video 47.1). Poor vision or damage to accessory instruments can result in patient injury.

Abdel-Razzak and Bagley reported two cases among 222 patients in which the procedure was stopped due to equipment failure, with iterative procedures being necessary [16]. In a series of 322 patients, Schuster *et al*. reported six incidents secondary to equipment failure [7].

Ureteroscope fracture during endoscopic procedures (Figure 47.1) was reported as having a very low incidence [11]. It can be avoided by careful handling of the rigid and semi-rigid ureteroscopes, during which the visual field must keep a perfectly round shape. When the endoscopic field shifts to a crescent-shaped image, instrument breakage is imminent.

A fractured flexible ureteroscope with locked deflection *in situ* requiring ureteroscope sectioning and open extraction was reported by Anderson *et al*. [17]. Guidewire breakage may occur due to deterioration induced by lithotripsy devices. When in direct contact, the holmium:YAG laser may cause ancillary instrument fracture, and the resultant fragments may require URS extraction. Balloon dilator breakage may lead to iatrogenic lesions of the ureteral wall, including perforations, urinary extravasations, or bleeding. This event may follow rapid balloon inflation or exceeding the recommended pressure, and can be avoided by insuring a gradual and carefully monitored pressure increase.

The real incidence of complications related to equipment malfunction is probably underestimated. Many of these events may be avoided by appropriate maintenance and handling during sterilization, storage, and use [5]. Flexible ureteroscopes are particularly fragile, thus requiring specific protection measures. During flexible URS, accessory instruments must be introduced without proximal end deflection in order to avoid deterioration of the working channel. The operator must be accustomed to the devices and instruments, operation mechanisms, and usual settings of lithotripsy equipment. In case of malfunction, the instruments should be replaced, or, if not possible, the procedure must be stopped immediately, in order to avoid major complications.

Figure 47.1 Fractured semi-rigid ureteroscope.

Retained basket

This incident occurs in about 0.5% of cases. The forced retraction of the basket in this situation may lead to an extremely serious complication, represented by the rupture of the ureteral wall in close contact with the calculi and eventual ureteral stripping.

In the majority of cases, this complication can be solved endoscopically, by unsheathing the basket followed by ureteroscope withdrawal [6]. Afterwards, the endoscope is inserted along the basket, and stone lithotripsy between the wires is performed until the extracting device is released (see Video 47.2).

Proximal calculus migration

Until recently, proximal calculus migration, which occurs in between 5% and 10% of cases [5], was considered an intraoperative incident and a significant cause of treatment failure. However, due to new treatment alternatives (and especially flexible ureterorenoscopy), ascending migration of the stone is no longer considered an intraoperative incident.

The risk of ascending migration depends on the initial location of the calculus, the type of energy source, as well as the degree of dilation of the upper urinary tract. Before the widespread use of flexible URS, this incident required subsequent treatment with ESWL or nephrolithotomy. Nevertheless, proximal migration of a calculus does prolong anesthesia and operative time, and may submit the patient to a second procedure.

The type of lithotripter has a significant impact on the risk of proximal migration, with higher rates after pneumatic and electrohydraulic lithotripsy than after holmium:YAG laser lithotripsy. Prevention of ascending migration may be achieved by placing the patient in a reverse Trendelenburg position or by minimizing the irrigation pressure.

Different devices have been developed to reduce the risk of proximal migration, e.g. balloon catheters or special devices (including Stone Cone, Stone Catcher, Accordian), which allow occlusion of the ureteral lumen above the stone [18]. A similar occlusion may be achieved using Backstop gel. This is a water-soluble, self-forming, polymeric plug with reverse thermosensitive properties, applied proximal to the stone, which can be dissolved

in saline and thereby removed at the end of the procedure.

Ureteral stent malposition

Ureteral stent malposition has a low frequency and is most likely to occur due to ureteral stenosis or tortuosity. It can be avoided by proper placement of the guidewire in the pyelocalyceal system and advancement under fluoroscopic guidance (see Video 47.3).

Intraoperative complications

Intraoperative complications of URS have reported incidence rates between 0.5% and 20% [7, 13, 19–21]. Most are minor and can be treated in a conservative manner by ureteral stenting without long-term consequences. These minor complications include false passage, mucosal abrasion, irrigation fluid extravasation, and ureteral wall perforation. Major complications are rare, with an incidence of 1.5–5%.

Mucosal abrasion

Mucosal abrasion occurs to some degree during all URS procedures (see Videos 47.4 and 47.5). Secondary bleeding and ureteral wall edema can reduce endoscopic visibility and maneuverability of the instruments. Postoperatively, minimal ureteral lesions may cause obstruction secondary to edema or clots.

After 248 procedures using large-caliber instruments (9.5F or 11.5F), Francesca *et al*. described a 24% incidence of ureteral mucosa lesions [3]. By comparison, the use of small-caliber instruments (6–7.5F) in 49 procedures was associated with a 6% incidence of mucosal abrasion.

Appropriate technique may decrease the incidence of ureteral abrasion and diminish its consequences. If multiple ureteroscope passages are required, the use of a ureteral access sheath can prevent a traumatic ureteral mucosa lesion.

Bleeding

Bleeding secondary to URS is usually minor. It often occurs due to either ureteral orifice trauma or lesions produced during guidewire advancement, or calculi handling or fragmentation. Bleeding reduces visibility during the procedure, and in extremely rare cases, its intensity may require the procedure to be stopped or additional measures taken to control it.

Blute *et al*. emphasized the fact that reduced visibility secondary to minor bleeding was the most frequent reason a repeat procedure was necessary [21]. Nevertheless, this complication was considered the primary complication in only 0.3% of the cases. In a series of 290 patients, Abdel-Razzak and Bagley reported a 2.1% incidence of bleeding severe enough to require the procedure to be stopped [16]. None of these patients required transfusion. Based on 1000 procedures, Grasso reported a 0.8% and 0.2% incidence of prolonged intra- and postoperative bleeding, respectively [22].

In a study of 37 patients on anticoagulant treatment, Turna *et al*. described no increased risk of hemorrhagic adverse events or decreased stone-free rates related to flexible ureterorenoscopy and holmium:YAG lithotripsy [23].

Thermal lesions

The use of heat-producing energy sources during URS may affect nearby tissues, causing various lesions from small mucosal defects to large necrotic areas.

The electrohydraulic lithotripter is associated with a significant temperature rise and high risk of ureteral thermal lesions. Basar *et al*. reported two perforations (1%) from electrohydraulic lithotripsy in a series of 207 ureteroscopies [24].

Some lasers are associated with a risk of thermal lesions. The Nd:YAG laser has a deep penetrability of 5–6 mm and therefore must be used with extreme caution in order to lower the risk of harming adjacent organs [25]. The energy produced by the holmium:YAG laser is absorbed by water, thus leading to thermal lesions in the range of 0.5–1 mm. Based on a trial of 598 flexible URS procedures, four complications were attributed to the holmium:YAG laser, of which one was a case of ureteral perforation and three of laser fiber fracture [26]. Although ureteral stenting alone may be sufficient in such cases, late complications can still occur [11]. Thermal lesions can be prevented by avoiding contact between the laser probe and the ureteral mucosa, and by placing the probe parallel to the wall.

Ureteral false passage

False passages may develop during insertion of the safety guidewire (Figure 47.2, Video 48.6), ureteroscope, or another instrument. These lesions consist of mucosal perforation without complete ureteral wall crossing (Figure 47.3). Often, false passages may occur when an attempt is made to overpass the stone with the guidewire.

Blute *et al*. reported a false-passage incidence of 0.9% in 346 URS procedures [21], while Grasso found an incidence of 0.4% for the same complication in a series of 1000 patients [22]. As for perforations (see below), the incidence of these events may be underestimated due to a failure to recognize the lesion during the procedure (see Video 47.7).

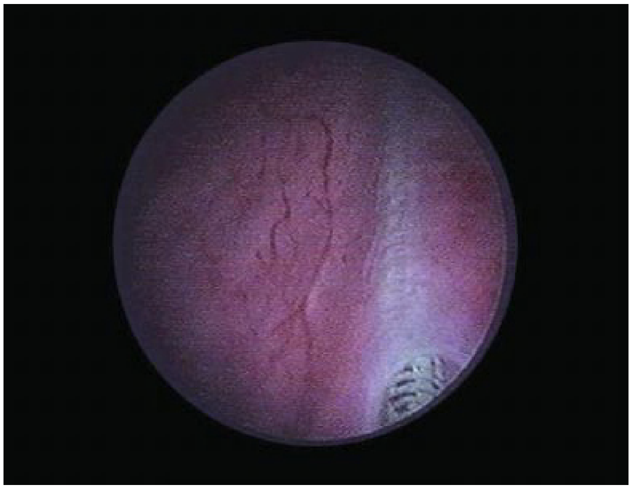

Figure 47.2 Submucous false passage produced with the guidewire.

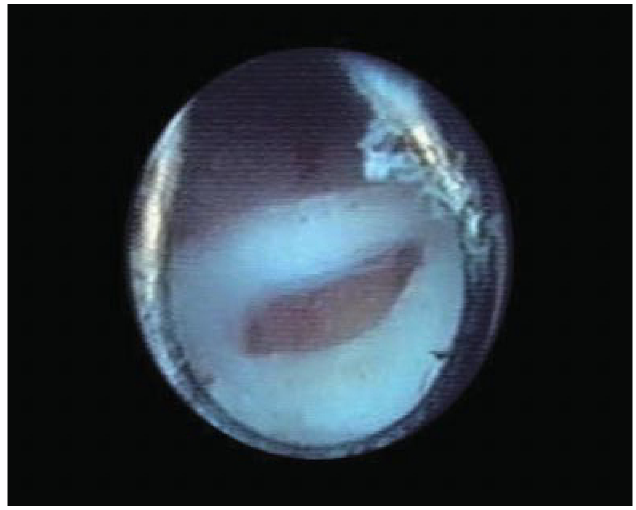

Figure 47.4 Ureteral perforation during trans-ureteroresection of transitional cell carcinoma.

Figure 47.3 Ureteral false passage.

Lytton *et al*. reported complete occlusion with ureteral necrosis following a false passage produced all along the ureter that occurred while advancing the ureteroscope [27].

Developing a false passage during guidewire insertion can be suspected if it is either difficult or impossible to advance. If there are doubts concerning the existence of ureteral mucosa lesions, contrast may be injected to confirm the guidewire position within the pyelocalyceal system. The appearance of periadventiceal extravasation of the contrast can certify the false passage and consequently the guidewire must be repositioned intraluminaly. Sometimes, this maneuver can only be performed under direct URS visual control [28].

Ureteral false passages produced during guidewire advancement can lead to serious lesions if later they act as passages for advancing catheters and other instruments of larger caliber. However, sequelae of false passages are usually minor. In most cases, double-J stenting for 1–2 weeks is enough. Small false passages that are limited to the mucosa can be treated in a conservative manner, without stenting.

Ureteral perforation

Perforations include small lesions that occur while advancing the guidewire, the laser fibers, or other accessory instruments on the one hand, and significant lesions caused by the tip of the ureteroscope or by calculi propulsion through the ureteral wall on the other (see Videos 47.8 and 47.9) .

The risk of ureteral perforation increases in cases of sinuosity, periureteral fibrosis (secondary to surgery or irradiation), or fixed calculi, or if there is sudden patient movement. General anesthesia is preferable to regional anesthesia for these patients, and an appropriate curarization is especially needed.

Perforation is recognized by observing the breach in the ureteral wall or the periureteral fat tissue (Figure 47.4). Careful handling of the ureteroscope under direct visual control may reduce this type of injury.

The incidence of ureteral perforation ranges from 0% in more recent studies involving flexible ureteroscopes [22] to as high as 17% in earlier series [29]. Stoller and Wolf assessed studies published between 1984 and 1992 and, based on 5117 URS procedures, reported a 6.1% incidence of ureteral perforation [30]. Stoller reported 24 perforations after 156 procedures (15.4%), 19 of which occurred in cases in which high-caliber ureteroscopes were used (12.5F) [14]. By contrast, Abdel-Razzak and Bagley reported a 1.7% rate of ureteral perforations

using 8.5–10.8F ureteroscopes [16]. Comparing the results of conventional ureteroscopes (9.5–11.5F) to those obtained using the low caliber ones (6–7.5F), Francesca *et al*. reported a ureteral perforation rate of 11.2% and 2%, respectively [3]. More recent studies have shown a less than 2% incidence for this complication [5]. Grasso reported no ureteral perforations in a series of 1000 URS procedures [22].

The reduction in incidence of ureteral perforation has occurred with the availability of small ureteroscopes and precise energy-releasing lithotripters, i.e. laser and pneumatic lithotripters rather than the older electrohydraulic ones, as well as increasing experience. However, ureteral perforation continues to represent a significant complication, carrying a major risk of ureteral stenosis.

The differentiation between large perforations and partial avulsions is difficult, but their treatment is largely similar. In most cases, ureteral perforation requires stenting for 2–6 weeks, and only exceptionally is open surgery or laparoscopy necessary. In a series of 1575 patients, Jeromin and Sosnowski reported 29 ureteral lesions, of which 20 were minor ureteral mucosa lesions, five were minimal perforations necessitating ureteral stenting, and four were severe perforations for which open surgery was mandatory [31]. In case of failed ureteral stenting, percutaneous nephrostomy or antegrade stent insertion is necessary. If the percutaneous or retrograde approaches are impossible, open surgery is required.

After the intervention, it is advisable to perform a careful follow-up of the patient in order to identify ureteral stenosis or fistula secondary to iatrogenic lesions.

Urinary extravasation

Urinary extravasation can occur following ureteral wall lesions and leads to retroperitoneal urinoma. According to several studies, the incidence of urinary extravasation is 0.6–1% [5]. However, because retrograde intraoperative pyelography is not a recommended routine procedure, it is possible that the real incidence of this complication may be underestimated. The degree of extravasation is directly related to the parietal lesion size as well as to the moment of perforation.

Small quantities of liquid extravasation do not usually have clinical significance. Nevertheless, important extravasations may have disadvantageous effects. Absorption of hypotonic irrigant may cause volume overload, hyponatremia, and hemolysis. Using saline solutions during URS may prevent this complication. Also, to avoid calyceal rupture or perforation, an appropriate irrigation pressure is recommended.

The existence of an associated urinary infection may cause retroperitoneal abscesses. Some studies have underlined the fact that urinary extravasation causes periureteral fibrosis. In case of significant extravasation, ureteral stenting or percutaneous nephrostomy may ensure an adequate drainage and ureteral healing without sequelae.

When postoperative urinary extravasation is suspected, intravenous pyelography exploration is mandatory (Figure 47.5).

Submucosal calculi migration

Stone fragment migration at the ureteral mucosa level (Figure 47.6) represents a complication for which the therapeutic approach remains controversial. Even though exteriorization of a stone fragment through the ureteral wall does not have long-term consequences, its stabilization at the submucosal level may cause

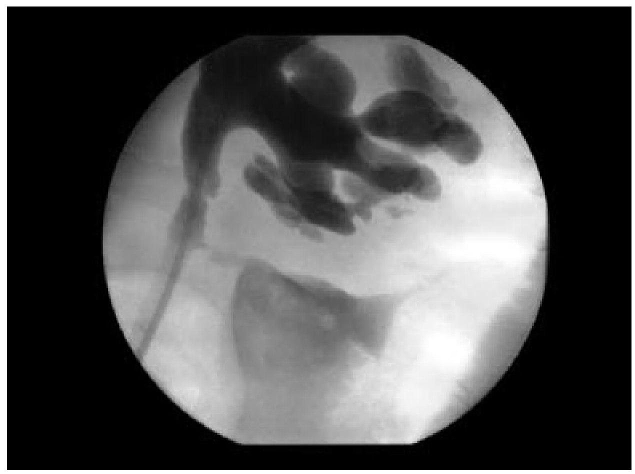

Figure 47.5 Ureteral perforation with contrast extravasation.

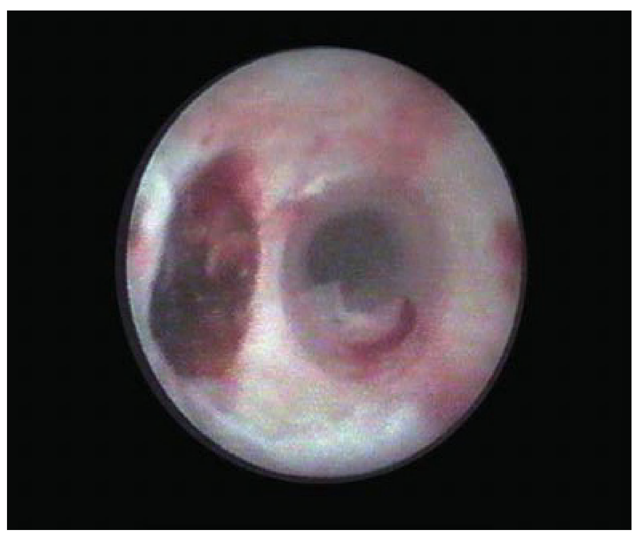

Figure 47.6 Stone fragment migrated through a ureteral wall perforation.

granuloma formation and subsequent ureteral stenosis. The extraction of these calculi is difficult (see Video 47.10), as it may lead to ureteral perforation, retroperitoneal urinoma, and secondary periureteral fibrosis.

Dretler and Young reported four cases of granuloma induced by calcium oxalate stone fragments imbedded in the ureteral wall during URS lithotripsy for cases of ureteral stenosis untreatable by ureteral dilation [32]. Grasso *et al*. revealed a high-risk of stenosis related to stone fragments imbedded in the ureteral wall less than 4 mm from the lumen [33]. It is for this reason that endoluminal ultrasound evaluation is recommended, and that fragments located less than 4 mm from the ureteral lumen should be extracted, while deeper migrated fragments may be left on-site with minimum risk of further complications. In many cases, the submucosal stone fragments can be identified from bulges seen on the ureteral wall during endoscopy, and no endoluminal ultrasonography is necessary.

Calculi stabilized at the submucosal level can be extracted by laser incision followed by prolonged ureteral stenting. When this approach is not possible, surgical resection of compromised ureteral segments is required.

When the obstruction occurs during the postoperative period, computed tomography (CT) may establish the presence of stone fragments near to the ureteral lumen or along the stent.

Extraureteral calculi migration

The incidence of extraureteral calculi or stone fragment migration is between 0.5% and 3.2% [11, 34–36]. Extruded stone fragments may be the result of an improper endoscopic technique associated with the presence of some predisposing factors [37]. Ureteral wall edema, poor blood supply in the injured zone, microtrauma of the ureteral mucosa, a high intraluminal pressure secondary to the irrigating fluid, and compression of stone fragments by the ureteral stent placed after the procedure are thought to be involved.

Extraureteral calculi migration does not usually cause clinical complications or require treatment [35, 36]. Despite this fact, the presence of a continuity solution within the ureteral wall may induce stenosis development or other late complications. Any attempt to advance the ureteroscope or to introduce different instruments through the breach in order to extract the stone fragments may widen the ureteral wall gap. When lithiasis is associated with urinary infection, a retroperitoneal abscess may develop.

Extraureteral calculi migration requires radiologic highlighting of fragments and the patient should be informed in order to prevent further potential diagnostic confusion [38]. Postoperative follow-up involves ultrasonographic monitoring in order to verify the absence of obstruction as well as upper urinary tract repercussions.

Intussusception

Ureteral intussusception during URS is a rare complication. It can occur in both directions and is more accurately an avulsion of the inner mucosal lining of the ureter [39]. This complication can follow forceful extraction of large ureteral calculi, in association with ureteral polypoid transitional cell carcinoma (TCC) after retrograde pyelography or URS.

Surgical resection and ureteral reimplantation are necessary to correct this complication.

Ureteral avulsion

Ureteral avulsion is a major intraoperative complication involving extensive lesions caused by ureteral elongations that lead to its rupture in the area of minimal resistance, most commonly the proximal third of the ureter (see Video 47.11).

Though very rare (0.2–1.5% incidence) [6, 13, 21], it is the most serious complication. The first two cases were reported by Hart in 1967 [40] and Hodge in 1973 [41], and both had occurred after difficult handling of ureteral stones using the basket probe. In a review by Stoller and Wolf assessing more than 5000 URSs, a 0.3% incidence of this complication was reported [30], but in another evaluation of 1059 patients between 1992 and 1998, no ureteral avulsions were reported [22].

Disregarding the basic rules of URS, such as inappropriate equipment, lack of ureteral orifice dilation when needed, misuse of baskets for calculi extraction, and visual deficiency during lithotripsy is of particular importance in the development of this complication. The major risk factors are use of multiple wire baskets, especially for stones larger than 1 cm, and large distance between calculi and ureteral orifice [42]. This has limited the use of baskets for stone fragment extraction in numerous centers. The risk of ureteral avulsion is also much higher during rigid URS [43]. Another potential factor involved in ureteral avulsion is the pre-existence of ureteral pathologic areas, either following a certain condition or secondary to previous endoscopic or open surgery procedures.

Ureteral avulsion can usually be diagnosed immediately it occurs during the procedure by recognizing the tubular structure engaged after the extraction maneuvers (Figure 47.7). Sometimes, the lesion can be identified through retrograde pyelography performed for suspicion of a ureteral lesion. In this case, there is complete extravasation of the contrast and no opacity in the ureteral segment above the lesion. On rare occasions,

Figure 47.7 Ureteral segment tractioned into the bladder after ureteral stripping.

late diagnosis may be established due to fever, lumbar pain, palpable lumbar tumor, retroperitoneal urinoma symptoms, or abscess secondary to urine extravasation [43]. In these cases, diagnosis must always be confirmed by ultrasound, CT, intravenous pyelogram (IVP), or retrograde pyelography.

Intraoperative recognition of this complication demands immediate surgery. If the lesion is diagnosed late or if the patient requires additional preparation or stabilizing measures, percutaneous nephrostomy is recommended until the definitive treatment is performed.

Open surgery and laparoscopy are the methods of choice in treating ureteral stripping, the objective being restoration of the ureteral continuity. Despite this fact, there are no distinct guidelines regarding the optimal treatment alternatives for this complication. When making a therapeutic choice, the patient's age, renal function, lesion location, and ureteral defect length must be considered. Some authors suggest that when ureteral continuity can be re-established by using the guidewire, ureteral stenting for a few months with the aim of secondary healing of the ureteral wall, may be attempted. However, this involves an important risk of ureteral stenosis.

If the distal ureter is affected by the lesion, the therapeutic choice may be ureteroneo-cystostomy. Sometimes, reimplantation may require "psoas hitch" or "Boari flap" procedures, or combinations of the two, but such techniques are limited to ureteral lesions located below the pelvic brim. Middle ureteral lesions may be treated through end-to-end anastomosis over the ureteral stent, providing the ureter is not devitalized. In case of complete ureteral avulsion from the ureteropelvic junction (UPJ), the first treatment of choice is pyeloplasty.

If tissue loss is important, autotransplantation (especially in younger patients) or ileum interposition may lead to good results [43, 44]. In the long-term, ureteroplasty using an ileum segment may lead to metabolic disorder. Another alternative to extensive lesion reconstruction may be appendix interposition [45]. Kidney autotransplantation is a viable alternative, even in cases with a short remaining ureter, and the long-term results are superior to those of ileum interposition. Very rarely, nephrectomy may be the most appropriate option in patients with a normal contralateral kidney as attempting to preserve the renal unit will bring additional risks [6].

Ureteral avulsion can be prevented by using an appropriate technique. Surgical experience, observing the basic URS rules, using small caliber instruments, avoiding basket stone removal, performing fragmentation before extraction, and obtaining a good visualization during lithotripsy are all important. Basket extraction of proximal or middle ureteral stone fragments must be performed with extreme caution. The recommended option is to use triradiate grasping forceps which allows calculi release in case of difficult extraction. If the stone cannot be safely removed, lithotripsy is recommended so that the resulting fragment can be easily extracted.

Partial ureteral avulsion

Partial ureteral avulsion is a rare complication which causes less severe sequelae than ureteral avulsion. If a safety guidewire has not been inserted during the procedure or if lesions cannot be overpassed, percutaneous nephrostomy with antegrade stenting is indicated [30].

Early postoperative complications

Infection/sepsis

Seeding infectious pathogens in the upper urinary tract during the procedure is a major cause of secondary urinary tract infections (UTIs). Likewise, handling potential infected calculi may induce sepsis. Using a high irrigation pressure in cases of UTI leads to bacteremia.

The incidence of fever during the immediate postoperative period is relatively high, but this does not always reflect UTI or bacteremia. The chemically-induced sterile kidney inflammation is sometimes the reason for fever [30]. In a series of 346 URSs, Blute *et al*. reported fever over 38°C as the most frequent complication (6.4%) [21]. According to Abdel-Razzak and Bagley, postoperative fever has an incidence of 1.2–1.3% [16].

Preoperative antibiotics reduce the risk of postoperative infections and fever. Jeromin and Sosnowski reported a 22% incidence of fever in a group of patients

in whom preoperative antibiotics were only administered in complicated cases, the UTI being diagnosed in 3.7% of cases [31]. Francesca *et al*. [3] diagnosed UTI in 22.5% of patients previously subjected to retrograde URS using high-caliber ureteroscopes and in only 4% of patients for whom small-caliber semi-rigid ureteroscopes were used [3]. No clear explanation was given for this difference.

The incidence of post-URS sepsis is low. Schuster *et al*. described a UTI incidence of 1.2% and a 0.3% sepsis rate [7], while Stoller *et al.* reported a 2% rate sepsis [14]. The literature does not establish a precise difference between infection and sepsis, which leads to extremely heterogeneous reports.

Even though sepsis or UTI may occur despite sterile preoperative urine, sterilization before the procedure must still be performed. Urine culture-based antibiotics are mandatory before the procedure, although prophylactic antibiotics for patients with sterile urine culture are controversial.

As already mentioned, reducing the irrigation pressure is important for preventing urinary infections and bacteremia, especially in case of infected lithiasis, although the pressure must be maintained high enough to allow good visibility. Lowering the upper urinary tract pressure can be achieved by using a ureteral access sheath [46], an angiographic catheter, or by emptying the collecting system via the ureteroscope. Additionally, continuous or discontinuous bladder drainage may help maintain a low pressure during URS.

Obstruction

Ureteral mucosa lesions induced by instruments maneuvered inside the upper urinary tract may lead to obstruction due to local edema, clot formation, and ureteral spasm. Ureteral stenting at the end of the procedure decreases the rate of this complication. The reported incidence of post-URS renal colic ranges from 4% to 9% [16, 22]. Harmon *et al*. reported a renal colic rate of 3.5%, with replacement of the ureteral stent being necessary in 2.6% of cases [13]. Obstruction is usually self-limiting and treatable by conservative measures.

In case of persistent pain, imaging evaluation is necessary to confirm the obstruction, determine its degree, and establish its location. Ureteral stenting may lead to remission of symptoms.

Vesicoureteral reflux

Vesicoureteral reflux may occur after URS, even if no ureteral dilation was previously performed. In a series of patients, Ritcher *et al*. highlighted a 10% reflux rate 24 h after URS was performed with a 13.5F ureteral orifice dilation [47]. Resolution of the reflux was demonstrated in all cases by repeating the cystography after 2 weeks. Other studies have reported the presence of reflux in 5–10% of patients 3–20 months after the procedure, most of whom having undergone intramural ureter dilation [14]. Using small-caliber semi-rigid or flexible ureteroscopes without ureteral orifice dilation may reduce the incidence of reflux.

Late postoperative complications

Late complications are extremely rare due to equipment improvement and growing endoscopic experience.

Ureteral stenosis

The incidence of post-URS stenosis ranges from 0% to 4%. These strictures (Figure 47.8) may occur as a consequence of ureteral trauma induced by the endoscopic procedure or following stone impaction leading to periureteral liquid extravasation, mucosal lesions, and wall ischemia, or even thermal lesions caused by endoluminal lithotripsy [19, 48].

Ureteral perforation at the level of impaction was considered the main risk factor for postoperative stenosis. Though Stoller *et al*. reported a global stenosis rate of 3.5% [14], this rose to 5.9% in patients with ureteral perforation. Based on a retrospective study in 21 patients with ureteral impacted calculi for more than 2 months, Roberts *et al*. reported a 24% complication rate after an average period of 7 months from the initial URS [48].

Figure 47.8 Ureteral stenosis following ureteroscopy.

The incidence of this complication has been significantly reduced following the miniturization of ureteroscopes, as well as equipment and technique improvement. Initial studies using 9.5–12.5F ureteroscopes reported postoperative stenosis rates higher than 4% [21], while in more recent evaluations the secondary stenosis rates in patients for whom low-caliber semi-rigid or flexible ureteroscopes were used were under 1% [3, 13, 16].

Some authors have assumed that use ofa ureteral access sheath may induce postoperative stenosis. Delvecchio *et al.* found only one case of ureteral stenosis after 71 URSs using this device [49].

All types of intraureteral lithotripsy have the potential to generate thermal energy that can causes mucosal lesions and eventually strictures. It appears that the highest temperatures occur with electrohydraulic lithotripsy. Additional factors such as previous irradiation lead to increased necrosis or a risk of ureteral devascularization after endoscopic handling. This event may eventually induce ureteral stenosis.

Due to the reduced rate of ureteral stenosis after the introduction of the newer generation ureteroscopes, some authors questioned the need for an imaging investigation as part of the follow-up. In the reassessment of 183 URS cases, Karod *et al*. found no ureteral obstructions among the 110 asymptomatic patients [50]. This complication was only found in one of the 21 patients with postoperative symptoms. Based on these data, the authors claim that post-URS imaging evaluation can be avoided in asymptomatic patients with no intraoperative lesions. However, Weizer *et al*. reported a 3.7% rate of asymptomatic obstruction and recommended routine imaging evaluation 3 months after the procedure in order to avoid potential complications of undiagnosed ureteral obstruction [51].

Careful handling of the ureteroscope, accessories, and stones, and minimizing ureteral trauma are important in the prevention of secondary stenosis. Performing dilation of narrowed ureteral areas can decrease the perforation rate as well as the risk of late ureteral stenosis. Ureteral stenting and repeating the procedure after 7–10 days can facilitate the URS approach.

In case of ureteral perforations, a double-J stent for 2–3 weeks may decrease the risk of stenosis [14]. The literature provides little data concerning the specific stenting time in these situations.

Postoperative ureteral stenosis requires endoscopic evaluation of the location and length of the affected area (see Video 47.12). The first treatment option is endoureterotomy as these strictures are generally nonischemic and short [52]. Balloon dilation followed by ureteral stenting is another viable alternative. Long ischemic strictures or cases of failed endoscopic treatment can benefit from open surgery or laparoscopy.

Persistent vesicoureteral reflux

Persistent ureteral reflux has a very low incidence, and most commonly occurs with ureteral dilation, ureteral orifice incision, or intramural tract lesions.

Vesicoureteral reflux rarely requires surgical treatment. Sterile, low-degree reflux in adults is usually of no consequence. Consequently, there is no need for routine radiologic reflux evaluation after URS [30].

Persistent vesicoureteral reflux may be treated by endoscopy, submucosal Teflon, bovine collagen or autologous fluid fat injection, or by creating different antireflux mechanisms [53].

Complications of ureteroscopic management in upper tract transitional cell carcinoma

URS treatment of upper urinary tract tumors was initially considered an option in patients with solitary kidneys, renal failure, bilateral TCC, or significant medical comorbidities. More recently, this approach was also indicated for renal preservation in patients with normal contralateral kidneys and small volume focal low-grade upper tract TCC [54].

The complications described in the literature are either similar to those related to other URS procedures or specific to upper urinary tract TCC treatment. The main differences are the incidence and mechanism of occurrence of ureteral perforation and stricture. With this procedure, there is a 2% risk of ureteral or pelvic perforation due to technical errors involving endoscopes, guidewires, baskets, and/or laser fibers. Grasso and Bagley reported no perforations in 101 patients treated for upper tract TCC [55]. However, Elliott *et al*. [56] and Martinez-Pineiro *et al*. [57] reported two and four perforations, respectively.

Perforation while using the holmium:YAG or Nd:YAG laser can occur if the power settings are too high, the ablation too deep, or the laser is directed to the ureteral or pelvic wall rather than to the tumor. The laser fiber tip should always be visualized a few millimeters beyond the distal end of the ureteroscope and directed at the tumor under visual control [54, 58].

Once a perforation is intraoperatively diagnosed, discontinuation of the procedure should be considered in order to prevent tumor seeding. Most perforations can be treated conservatively by ureteral stenting. Larger perforations may require percutaneous drainage or even nephroureterectomy [54].

The incidence of ureteral strictures after treatment of upper tract TCC has ranged from 5% to 25% [58]. The risk of scarring and stricture formation is higher after extensive laser ablation of the tumor and adjacent ureter. Chen and Bagley reported ureteral stricture formation

in 12 of 139 patients (8.6%) [54]. Elliot reported six ureteral strictures in a group of 54 patients, three or whom were treated with the Nd:YAG laser and three with electrocoagulation [56].

Strictures discovered during the follow-up period must be biopsied to rule out a malignant stricture.

Another significant complication of the upper urinary tract tumor endoscopic approach is incomplete resection. The incidence is higher for tumors over 1.5 cm or located in the lower pole of the kidney. In these cases, a second treatment could be an option for low-grade tumors. In high-grade, large or multifocal tumors, nephroureterectomy should be considered.

Tumor cell seeding during URS were assumed due to the elevated irrigation pressure. However, studies on significant numbers of patients with upper urinary TCC treated by nephroureterectomy after URS did not reveal any malignant cell seeding [59].

Andrews and Segura described a renal pelvic explosion during URS fulguration of a papillary TCC, probably due to ignition of hydrogen (secondary to tissues coagulation) with the oxygen introduced during the procedure [60].

Complications of ureteroscopic incision

URS incisions can be used to treat a variety of upper tract obstructive processes, including ureteral and UPJ stenosis or calyceal diverticulum.

Ureteroscopic incision can lead to nonspecific as well as specific complications related to stenosis incision. Regarding specific complications, the most important one is bleeding secondary to incision, by injuring crossing vessels of the UPJ. The management of these complications includes various measures from watchful waiting associated with hemodynamic balancing to selective arterial embolization, or, in extreme cases, open surgery including nephrectomy. Various diagnostic methods such as endoluminal sonography and CT allow better detection of crossing vessels, thus leading to a considerable decrease of this complication [61]. Moreover, these methods, along with selective embolization, significantly reduce the number of cases requiring nephrectomy [62].

Measures to prevent complications

Patient selection and appropriate procedure planning are crucial for a successful intervention.

In order to prevent traumatic lesions of the ureter, a refined surgical technique is necessary for every operative step [11]. There is an obvious correlation between the complication rate and the endoscopic equipment and surgical skills. The routine use of a safety guidewire adjacent to the ureteroscope during upper tract endoscopy is considered essential in order to avoid or to solve the complications. However, some authors consider that the presence of a safety guidewire adjacent to the endoscope may prevent its passage. They claim that technologic advances in ureteroscope design and use of the holmium laser lithotripter minimize ureteral trauma and obviate the need for routine use of a safety guidewire during URS [63].

Appropriate equipment and accessory instruments are mandatory for a safe procedure. Any URS procedure must be performed under fluoroscopic guidance. While introducing the ureteroscope, any forced maneuver must be avoided. Excellent visibility should be maintained throughout the intervention.

If it is not possible to completely fragment the calculi or vision is reduced due to bleeding, the procedure should be stopped a ureteral stent placed, followed by a second-look URS. This approach is preferable to continuing with the initial intervention, which carries an increased risk of ureteral lesion.

Iatrogenic lesions are more common during the early phase of the learning curve, and consequently, the risk of serious complications is much higher for the inexperienced endoscopists. Nevertheless, with greater experience, more difficult cases will be approached, thus maintaining the probability of complications at a certain level.

Carefully performed URS is a superb tool for both diagnostic and therapeutic purposes and has a low rate of complications. The majority of these events can be corrected by conservative management.

CHAPTER 48

Ureteroscopy into the Future: Robotic Ureteroscopy

Monish Aron

USC Institute of Urology, Keck School of Medicine, University of Southern California, Los Angeles, CA, USA

Introduction

The use of retrograde flexible ureteroscopy is routine for a variety of diagnostic and therapeutic applications involving the upper urinary tract. This has been the result of advances in flexible ureteroscope technology, holmium:YAG laser lithotripsy, and ureteroscope accessories such as irrigation systems, wires, baskets, graspers, forceps, and access sheaths. Despite major technologic developments that include better control of deflection, improved optics and working channel diameter, increased durability despite miniaturization, flexible ureteroscopy in its current form has limitations. These include lack of stability and fixity of the scope tip, fragility, poor ergonomics, need for an assistant, limited range of motion within the collecting system, and radiation exposure due to the proximity of the surgeon and assistant to the operating table and C-arm.

Computerized catheter control systems

Computerized catheter control systems (CCSs) are currently being developed and refined, primarily for cardiac applications. This development is driven by the need for accurate positioning and manipulation of a catheter tip in the three-dimensional (3D) cardiovascular space. Such systems employ either remote navigation in a magnetic field or a computer-controlled electromechanical flexible robotic system [1–3].

Endovascular procedures such as cardiac electrophysiologic ablations are technically complex, requiring a high-degree of precision and reproducibility. Accurate control of fine movements and sustained stability of an ablation catheter or endoscope tip is usually suboptimal using simple manual control when performing complex procedures. Manual control of catheters and flexible endoscopes faces several challenges:

- Most existing technologies are best suited for movement and navigation within relatively straight tubular structures;
- Animate organs, however, are comprised of complex 3D tissue spaces, the successful negotiation of which requires complex movements of catheters and scopes;
- Existing manual control mechanisms are relatively crude and are not designed for sustained stable positioning of the tip of a catheter or flexible endoscope;
- Using manual control to navigate within complex 3D tissue spaces requires considerable experience and a combination of complicated maneuvers, including insertion, rotation, and articulation, which is somewhat arbitrary and not always precisely reproducible;
- The long duration of many procedures exposes the physician to more X-ray radiation and nonergonomic strain than is desirable.

These challenges present the need for a computerized robotic platform that allows precise, fully controllable, complex maneuvers of a variety of flexible endoscopes and steerable catheters inside hollow organs, tissue

Smith's Textbook of Endourology, Third Edition. Edited by Arthur D. Smith, Gopal H. Badlani, Glenn M. Preminger, Louis R. Kavoussi.

spaces, and body cavities. Such a system should allow accurate surgical manipulation within these small spaces, thus transferring the maneuverability advantages of a rigid robotic system into the endoluminal environment.

While almost all ongoing research and development in this arena centers around cardiac electrophysiologic and endovascular applications, there is reason to believe that these systems can be adapted for use in almost all specialties that require advanced diagnostic or therapeutic flexible endoscopy.

To improve catheter manipulation during a cardiac electrophysiologic procedure, new tools based on robotic manipulation and navigation of cardiac catheters are being developed. One such system is a novel magnetic navigation system, Niobe (Stereotaxis, St Louis, MO, USA), which allows remote computer-controlled navigation of a magnetic catheter tip [1, 2]. The system utilizes two computer-controlled magnets located on opposite sides of the patient, which create a magnetic field. A small magnet in the catheter tip causes the movement of the catheter to be fully controlled within the external magnetic field. The movement of the catheter is motorized, allowing remote navigation. This system has reportedly been used for a remote cardiac ablation procedure, where the physician located in Boston treated a patient located in Milan, in real time [4]. Another CCS, Sensei™, that relies on computerized electromechanical manipulations has been introduced by Hansen Medical System (Mountain View, CA, USA). This CCS consists of a workstation console, an electronics rack, a steerable catheter system, and a remote catheter manipulator that is attached to the operating table with a pivot clamp. The workstation console has a joystick-like input device that allows precise control of the steerable catheter system, as well as three liquid crystal display (LCD) monitors that can provide information to the operator, such as from a C-arm, an endoscope camera, patient physiologic parameters, as well as an in-built mechanism to show the exact position of the catheter tip in 3D space.

Our hypothesis is that such a computerized CCS could potentially obviate some of the limitations of manual flexible ureteroscopy by providing a stable, readily maneuverable, and ergonomically superior platform. To test this, we used modified software and catheter configuration from the original system designed for cardiac applications [3] to determine the technical feasibility of robotic retrograde flexible ureterorenoscopy, initially in the acute porcine model [4, 5] and then in humans [6, 7].

Laboratory experience

In July 2007, the first animal experiments in ureteroscopy with the modified robotic CCS, Sensei™, were performed. The procedure was performed bilaterally in five acute female swine (27–51 kg) after approval from the Institutional Animal Care and Use Committee.

The equipment

The robotic catheter control system (Figure 48.1) is comprised of the following components surgeon console including the three LCD displays and master input device (MID); electronics rack; remote catheter manipulator (RCM), and steerable catheter system.

Surgeon console (operator workstation)

The surgeon console (Figure 48.2) consists of the MID, three display monitors, one touch screen, an electronics control panel, and a user interface pendant. The MID is a 3D joystick that the surgeon uses to remotely manipulate the catheter tip. The display monitors allow simultaneous visualization of the endoscopic and realtime fluoroscopic views. Facility also exists to incorporate and synchronize other imaging modalities, such as computed tomography (CT) scan or realtime ultrasonography. The surgical console also includes an electronics control panel which communicates with the electronics rack, controls the MID, and contains the workstation fault detection and mitigation hardware and software.

Steerable catheter system

The steerable catheter system (Figure 48.3) contains an outer catheter sheath (14/12F) and an inner catheter guide (12/10F). Movement of the MID intuitively controls the tip of the catheter guide. The ureteroscope (which was inserted into the inner catheter guide) used in our initial animal study was a custom-built passive fiberscope that incorporated two fiberoptic light bundles and a 6000 pixel optical bundle providing a 70º field of view. It also had a 3.4F central working channel for introducing accessories and providing outflow for the irrigant. Consequent to this animal study, the outer diameter of the ureterorenoscope was reduced from 8.5F to 7.0F to increase the space between the scope and guide, and provide an adequate channel for pressurized irrigation. The catheter guide also has a channel for injection and efflux of irrigant and/or contrast. The ureteroscope is introduced through the catheter guide and is manipulated by movements of the guide, which are controlled by the MID.

Remote catheter manipulator

The RCM (Figure 48.4) is the arm that fixes to the operating table using a simple clamp. The steerable catheter outer sheath and inner guide are mounted on the RCM. The RCM incorporates a single set-up joint for optimal positioning.

Electronics rack

This contains all the hardware, including the computers, power supplies, and video distribution units.

Operative technique

Under general anesthesia, a 0.035-inch glidewire (Microvasive, Natick, MA, USA) was introduced cystoscopically into the ureteral orifice of the pig and positioned in the renal collecting system under fluoroscopic guidance. The outer catheter sheath and inner guide were inserted manually over the glidewire using an obturator. The obturator was removed and the ureteroscope introduced into the renal pelvis through the lumen of the inner guide. The catheter sheath, catheter guide, and ureteroscope were then mounted on the RCM (Figure 48.5). The RCM was draped with impervious plastic drapes to prevent fluid leakage onto the electronic components. Contrast was injected through the working channel to delineate pelvicalyceal anatomy. Each calyx was accessed ureteroscopically by remote manipulation via the MID. The robotic system software has two modes in which the catheter guide can be manipulated: fluoroscopic mode and endoscopic mode, that can be viewed simultaneously (Figure 48.6) or readily interchanged by pressing a button on the console. In addition, it is possible to determine the location and orientation of the scope tip in the collecting system by looking at the colored and shaded catheter animation on the LCD display (Figure 48.6). In two animals (four kidneys), three to five human stones from our stone collection, each approximately 4 mm in size, were introduced into the renal collecting system through the outer sheath. A holmium laser fiber was introduced into the working channel by the bedside assistant. Fragmentation was performed remotely using a 365–200 µm holmium:YAG laser fiber (Stonelight, Mountainview, CA, USA) set at 10 W (1.0 J, 10 Hz). In one animal (two kidneys), one papilla from each calyceal group (total six papillae) was laser ablated. An autopsy was performed

Figure 48.5 Acute porcine study with the steerable catheter and guide assembly mounted on the remote catheter manipulator. The custom-built ureteroscope was inserted through the inner guide. An endoscope camera was attached to the external end of the ureteroscope. The movements of the outer sheath and inner guide (and hence the ureteroscope) were controlled by movements of the joystick-like master input device on the surgeon console.

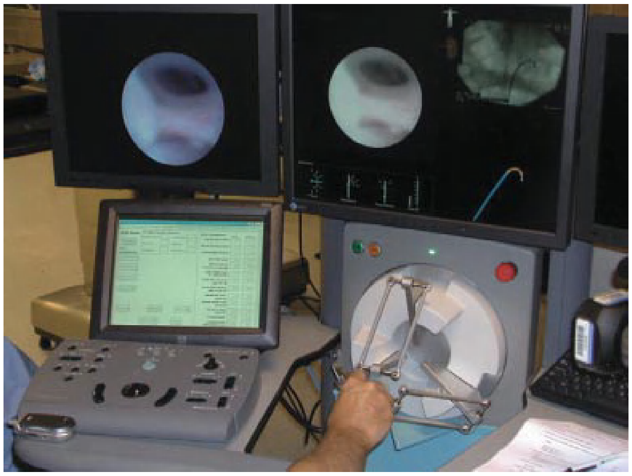

Figure 48.6 Porcine robotic ureterorenoscopy in progress. Endoscopic and fluoroscopic views can be seen simultaneously on the same or adjacent screens on the workstation. The computerized system also simultaneously displays the orientation of the catheter and location of the catheter tip in 3D space in the form of a realtime animation (arrow, blue – outer sheath, orange – inner guide)

at euthanasia and the kidney with entire length of ureter was harvested and submitted for histologic evaluation.

Specific parameters utilized to evaluate feasibility, safety, and performance of remote robotic ureterorenoscopic manipulations included the following:

- Need for ureteral dilation to accommodate the 14F outer sheath;
- Ability and time taken to access each minor calyx;
- Reproducibility of access into each minor calyx evaluated by success in re-entering each minor calyx three times;
- Ability to fragment intrarenal calculi and laser-ablate renal papillae;
- Stability of the system evaluated by the ability to "park" the ureteroscope tip at a desired location for a continuous 3-minperiod with the object in constant and optimal view;
- Reproducibility of the autoretract mechanism evaluated by being able to retract the scope tip to the original position;
- Integrity of the collecting system on retrograde pyelography;
- Evidence of ureteral and pelvicalyceal injury on gross and microscopic examination.

To objectively evaluate performance of the system as regards scope tip stability, reproducibility, and autoretract function, the surgeon completed a visual analog score (VAS) at the end of each procedure. The VAS was rated on a scale of 1 to 10, with 1 being the worst possible and 10 being the best possible performance.

Results

Balloon dilation of the intramural ureter was required in two of 10 porcine kidneys (20%) to accommodate the outer sheath of the robotic catheter system. Of the 85 calyces in the 10 kidneys, 83 (98%) could be adequately inspected with the flexible robotic system. Two lower pole minor calyces, one in each kidney of animal number 5 (weight 32 kg), could not be entered due to their small ostial size; however, a 3F basket could be passed into both these calyces under direct endoscopic vision. The time required to inspect the entire collecting system (mean 4.6 min) ranged from 15 min to 49 s, decreasing with experience from animal 1 through animal 5 (kidney 1 through kidney 10). All calculi could be fragmented with a laser fiber to a size smaller than the apparent diameter of the laser fiber in the four kidneys inserted with calculi. On the VAS, the stability of the system was rated at 10/10, reproducibility of access into each calyx at 10/10, and reproducibility of the autoretract mechanism at 8/10. Inaccuracies in the ability of the autoretract mechanism to return to the original vantage point were attributed to the movement of the UPJ with respiration. On retrograde pyelography, the collecting system was intact in nine kidneys (90%), and a perforation was noted at the ureteropelvic junction in one kidney (10%). This perforation occurred at the end of instrumentation due to surgeon error while retracting the robotic catheter in the flexed position. At autopsy, significant extravasation of irrigant was found in the retroperitoneum and peritoneal cavity in all five animals. Subsequently, the size of the prototype ureterorenoscope was reduced to 7.0F, thereby using the space between the ureteroscope and the guide catheter for infusion, and using the working channel space for efflux. Following this modification, ureterorenoscopy was performed in an additional animal and no retroperitoneal extravasation of irrigant at autopsy was observed. Furthermore, in the same animal, the measured volume of outflow (irrigant + urine) was slightly higher than the volume of inflow, thereby indicating adequacy of irrigant drainage.

Clinical experience

Based on lessons learned from the preclinical study and improvements made in the system, the first clinical study of flexible robotic ureterorenoscopy was performed after IRB approval. Robotic flexible ureterorenoscopic manipulations were performed in 18 patients with renal calculi using the modified Sensei™ system [6, 7]. Patients with solitary unilateral renal calculi measuring from 5 to 15 mm in size were included. Exclusion criteria were coexisting ureteral calculi or obstruction, uncontrolled infection, renal insufficiency, or solitary

kidney status. Mean stone size was 11.9 mm. All patients were prestented for approximately 2 weeks. The robotic catheter system was introduced manually into the renal collecting system under fluoroscopic guidance over a guidewire. All intrarenal maneuvers, including stone relocation and fragmentation into 1–2-mm particles, were performed remotely by the surgeon seated at the robotic console (Figure 48.7). All procedures were technically successful, and all calculi were fragmented to the surgeon's satisfaction, without need for conversion to manual ureteroscopy. Mean operative time was 91 min, including a robot docking time of 7 min. Stone localization time was 9 min. The mean visual analog scale rating (from 1, worst, to 10, best) for ease of stone localization was 8.3, ease of maneuverability was 8.5, and ease of fragmentation was 9.2.

Figure 48.7 Clinical robotic ureteroscopy in progress. A calculus in the right kidney was located and fragmented with a holmium laser by the surgeon comfortably seated at the robotic workstation far from the radiation source

Complete fragment clearance was achieved in 56% of patients at 2 months, based on CT examination (Figure 48.8), and in 89% of patients at 3 months, based on intravenous urographic examination. One patient required secondary ureteroscopy for a residual stone.

Complications included pyelonephritis in two patients, pyrexia in one patient, and temporary positional limb paresis in one patient. There was negligible fluid absorption, based on calculated inflow and egress and on ethanol fluid absorption testing.

Future directions

The results of the initial porcine experiments and clinical trial are encouraging, although considerable refine-

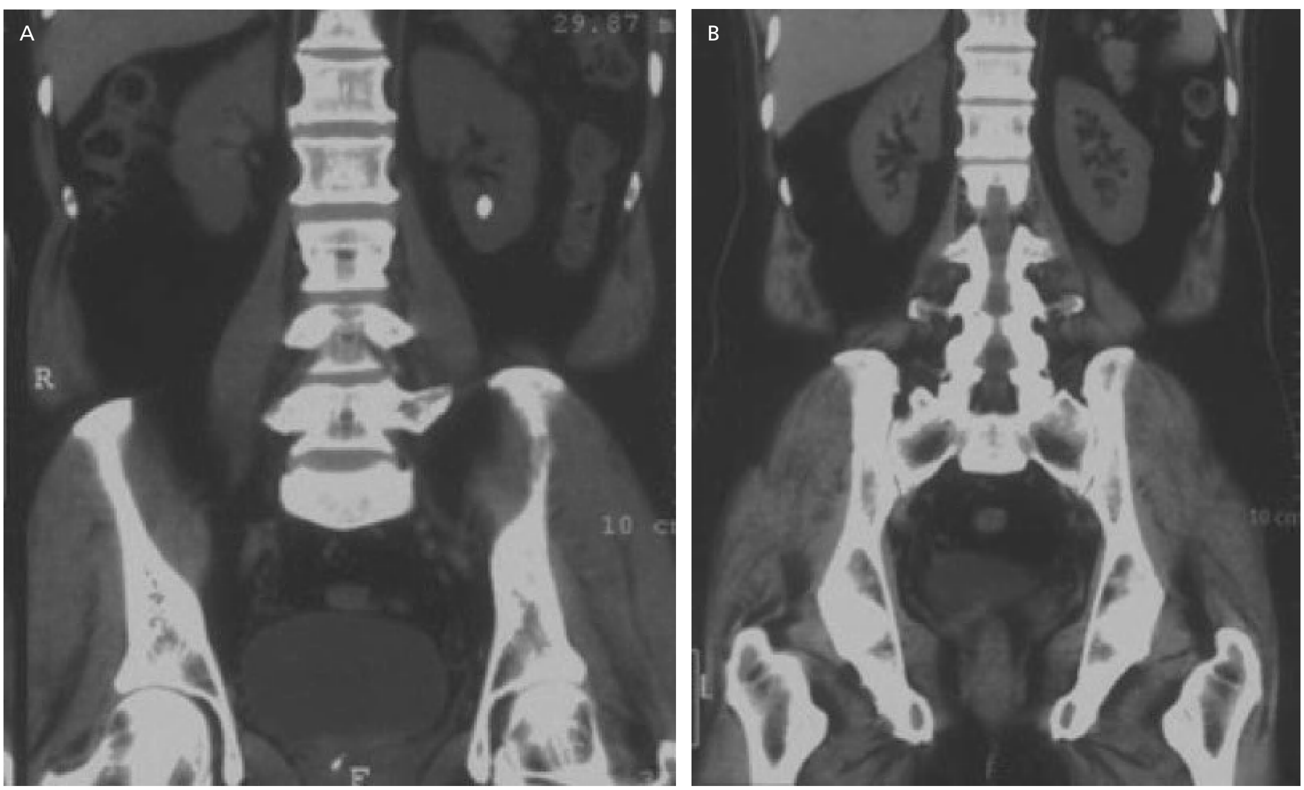

Figure 48.8 Clinical robotic ureteroscopy (URS). (A) Left inferior calyceal calculus prior to robotic URS and laser lithotripsy and(B) complete clearance 2 months after robotic laser lithotripsy

ments are still necessary. The system used for these experiments was not specifically designed for endourologic applications. This needs to be addressed for this to become a clinical reality. Whether or not industry will invest in this is dependent largely on market forces, and not so much on technologic limitations.

The ideal diameter of the outer sheath and consequently the other components is a matter of much debate. Remote robotic control of irrigation flow rate, introduction of wires, baskets, graspers, and laser fibers, as well as injection of iodinated contrast can potentially be incorporated into the system. Further refinements in robotic technology have the potential to provide additional benefits, such as automated movements and realtime surgical navigation utilizing realtime as well as archived imaging studies. Potential advantages of robotic ureteroscopy include precise control of the scope as well as enhanced stability, superior ergonomics, and decreased radiation exposure. Cost issues are important but undetermined at this time. The cost of ownership of the system for endourologic use is not known at this time since the system is not commercially available at this point. Nevertheless, it appears likely that the role of flexible catheter-based robotics in urology and other specialties is poised to expand for various intraluminal, transluminal, and laparoscopic applications. Further studies are necessary to determine the future role of emerging flexible robotic technology in surgical endoscopy.

SECTION 4
Shock-Wave Lithotripsy

CHAPTER 49
Physics of Shock-Wave Lithotripsy

Robin O. Cleveland[1] & James A. McAteer[2]
[1]Department of Engineering Science, University of Oxford, Oxford, UK
[2]Department of Anatomy and Cell Biology, Indiana University School of Medicine, Indianapolis, IN, USA

Introduction

Shock-wave lithotripsy (SWL) was introduced in the 1980s for the treatment of urinary stones and earned near-instantaneous acceptance as a first-line treatment option [1]. At that time, SWL revolutionized treatment in nephrolithiasis worldwide and within one decade it was reported that more than 85% of patients in Europe and the USA were treated with lithotripsy [2, 3]. Since then, the use of SWL has been in decline and it has been estimated that around 70% of kidney stones were treated using SWL in 2002 [4] but less than 50% in 2005 [5]. Over the years lithotripsy has undergone several waves of technologic advance, but with little change in the fundamentals of shock-wave generation and delivery. That is, lithotripters have changed in form and mode of operation from a user perspective, and in certain respects the changes have been dramatic, but the lithotripter pressure pulse is still essentially the same. Lithotripters produce a signature waveform, an acoustic shock wave. This pressure pulse, or shock wave, is responsible for breaking stones. However, it is also responsible for collateral tissue damage that in some cases can be significant [6–11].

Lithotripters produce a powerful acoustic field that results in two mechanical forces on stones and tissue: (1) direct stress associated with the high amplitude shock wave; and (2) stresses and microjets associated with the growth and violent collapse of cavitation bubbles. Recent research has made significant advances in determining the mechanisms of shock-wave action, but the story is by no means complete. What fuels this effort is the realization that a totally safe, yet effective lithotripter has yet to be developed. For example, one trend in the evolution of SWL has been the development of lithotripters that produce very high amplitude and tightly focused shock waves, motivated by the desire to deliver more energy directly onto the stone. However, clinical data suggest that the use of tightly focused shock waves results in increased adverse effects and higher retreatment rates [4, 12–16], and basic research suggests that many shock waves miss the stone [17] and those that do interact with the stone do not result in effective stone fragmentation [18, 19]. In the past few years, manufacturers have started to widen the focal zone of their lithotripters, a move that takes advantage of new findings on the mechanisms of stone breakage with the potential to improve performance (see Focal zone of the lithotripter, below).

A major objective within the lithotripsy community is to find ways to make SWL safer and more efficacious. The perfect lithotripter may not exist, so urologists are left to determine how best to use the machines at hand. One step toward improving outcomes in SWL is to have a better understanding of how current machines work.

This chapter introduces the basic physical concepts that underlie the mechanisms of shock wave action in SWL. Our aim is to give the background necessary to appreciate how the design features of a lithotripter can affect its function. We also present a synopsis of current theories of shock-wave action in stone breakage and tissue damage and summarize recent developments in lithotripter technology.

Smith's Textbook of Endourology, Third Edition. Edited by Arthur D. Smith, Gopal H. Badlani, Glenn M. Preminger, Louis R. Kavoussi.

Characteristics of a lithotripter shock wave

A typical shock wave measured at the focus of a lithotripter is shown in Figure 49.1A. The wave is a short pulse of about 5 µs duration [1 microsecond (µs) = 1 millionth of a second]. In this example the wave begins with a near instantaneous jump to a peak positive pressure of about 40 MPa [1 megaPascal (MPa) is about 10 atmospheres of pressure]. This fast transition in the waveform is referred to as a "shock." The transition is faster than can be measured and is less than 5 ns in duration [1 nanosecond (ns) is 1 billionth of a second]. The pressure then falls to zero about 1 µs later. There is then a region of negative pressure that lasts around 3 µs and has a peak negative pressure of around −10 MPa. The amplitude of the negative pressure is always much less than the peak positive pressure and the negative phase of the waveform generally does not have a shock in it, i.e. there is no abrupt transition. The entire 5-µs pulse is generally referred to as a shock wave, shock pulse or pressure pulse; however, technically it is only the sharp leading transition that is formally a shock.

Figure 49.1B shows the amplitude spectrum of the shock pulse, i.e. the different frequency components in the pulse. It can be seen that a lithotripter shock wave does not have a dominant frequency or tone, but rather its energy is spread over a very large frequency range; this is a characteristic feature of a short pulse. It can be seen that most of the energy in the shock wave is between 100 kHz and 1 MHz. This means the analogy of an opera singer shattering a crystal glass by singing at the right pitch (single frequency) is not appropriate for lithotripsy due to the multitude of frequencies present.

The waveform shown in Figure 49.1A was measured in an electrohydraulic lithotripter (a description of different types of shock wave generators is given below). Most lithotripters produce a similar shaped shock wave and in Figure 49.2A waveforms measured in an electrohydraulic lithotripter and an electromagnetic lithotripter at a high power setting are compared. It can be seen that both waveforms have a form that is common to all shock waves used in lithotripsy: a high amplitude compressive phase of extremely rapid transition (<1 ns) and short duration (~1 µs) followed by a trailing tensile phase (~3 µs). In this case the amplitude of the peak positive pressure of the electromagnetic lithotripter is 2.5 times that of the electrohydraulic lithotripter. In general, pressure amplitudes are machine and setting specific, and the peak positive pressure can vary from 20 to 110 MPa and the negative pressure from −5 to −15 MPa. For example, Figure 49.2B shows waveforms measured at lower power settings of both machines, and again the waveforms are similar but the peak amplitudes differ by less than 50%. Further, the spatial dependence of the pressure field is also machine and setting specific and this will be discussed below.

Acoustics primer for shock-wave lithotripsy

What is an acoustic wave?

An acoustic wave, or sound wave, is created whenever an object moves within a fluid (a fluid can be either a gas or liquid). In Figure 49.3 it is shown that as an object moves, it locally compresses the fluid that surrounds it, i.e. the molecules are forced closer together. The region of compressed molecules in turn pushes against the molecules next to it. This relieves the compression in the first region but leads to a new compressed region. The molecules in the second region then start to compress the next

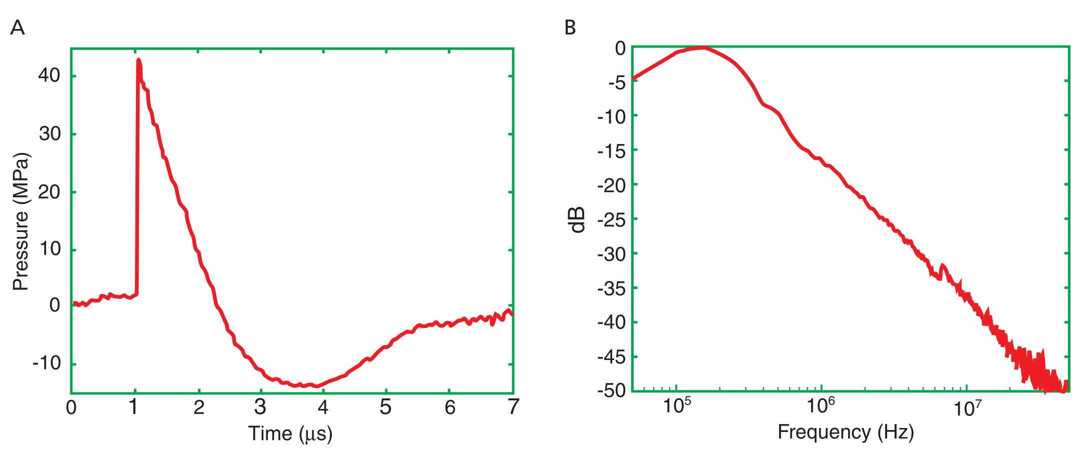

Figure 49.1 (A) A pressure waveform measured at the focus of an electrohydraulic lithotripter (Dornier HM3). (B) Fourier transform of the waveform in A showing how the energy is distributed as a function of frequency. Both axes are shown on a log scale. The peak of the amplitude response is around 300 kHz, which corresponds to a duration of 4 µs. It can be seen that this persists until frequencies of about 20 MHz.

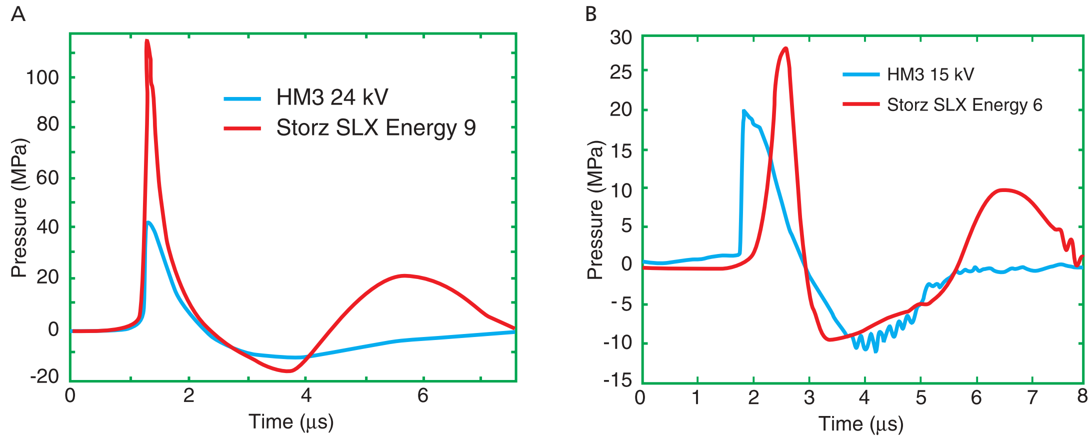

Figure 49.2 (A) Focal waveforms measured in the Dornier HM3 at 24 kV and the Storz SLX at Energy level 9. (B) Comparison at lower settings: the amplitudes are about the same but the SLX waveform has not formed a shock.

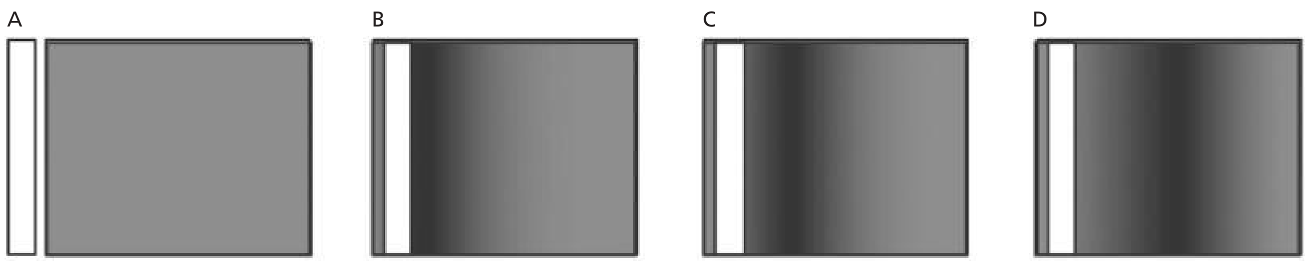

Figure 49.3 Molecular view point of a sound wave. (A) Medium is at rest. (B) A piston pushes all the molecules out of the left side, resulting in a localized region of compression at the face of the piston (dark region). (C) The neighboring molecules are compressed and the compression region moves away from the piston. (D) The wave continues to move away from the piston while the molecules at the piston return to their initial condition.

adjacent region and so on; it is thus that a "wave" of compression travels through the fluid. This is an "acoustic wave" and the speed of wave propagation (called the sound speed) is a material property of the medium; for air it is about 340 m/s, and in water and most soft tissues in the body it is about 1500 m/s. Note that individual molecules do not travel with the acoustic wave, rather they just jostle their adjacent neighbors. Therefore, for an acoustic wave to propagate, there must be a medium present that can support the vibrations. This is an important physical difference between classical waves (e.g. acoustic waves, seismic waves, water waves) and electromagnetic waves (e.g. light, radio waves, X-rays). For electromagnetic waves energy is carried by photons, which may be thought of as particles, which physically travel through space; thus, a medium is not needed for the signal to be transferred. Therefore, light can travel through a vacuum but sound cannot.

Sound waves have compressive and tensile phases

The explanation above describes the compressive phase of a sound wave, i.e. where the molecules are compressed. For the case where the object moves away from the fluid, there is a resulting rarefaction of the molecules, i.e. the moving object leaves a partial vacuum. In this case, the neighboring molecules will move to fill the void, leaving a new region of rarefaction. This continues one region to the next and the rarefractional disturbance propagates through the medium as a tensile acoustic wave. In most cases a tensile wave propagates just like a compressive wave and with the same sound speed.

Typical acoustic sources, such as audio speakers, vibrate backwards and forwards. This produces alternating compression and rarefaction waves that are referred to as the compressive phase and tensile phase of the acoustic wave. Often the waveform is sinusoidal in nature. Note, however, that the majority of acoustic waves, including the acoustic pulses generated in lithotripsy, are not sinusoidal in form. For small-amplitude waves (linear acoustics) every point of the waveform moves at the same speed, the sound speed c_0. This is a material property and for water and tissue it is about 1500 m/s. It will be shown later that for large amplitude (nonlinear) acoustic waves, such as shock waves, the

sound speed is slightly changed by the presence of the wave.

The waveform shown in Figure 49.1 displays the pressure pulse as a function of time at a given point in space. This is typically how acoustic waves are measured, e.g. a microphone will record how pressure varies in time at one point in space. However, acoustic waves also vary in space and it is often useful to think of the wave in terms of its spatial extent. The relationship between the temporal separation of points on an acoustic wave (Δt) and the spatial separation of the points (Δx) is given by:

$$\Delta x = \Delta t\, c_0 \qquad \text{(Eq 49.1)}$$

Recall that in water or tissue the c_0 is 1500 m/s (1.5 mm/μs) and therefore, for the shock wave shown in Figure 49.1, the positive part of the wave (a portion 1 μs long in time) will have a spatial extent in water of 1.5 mm. For a sinusoidal wave, the spatial extent of one cycle of the wave is called the *wavelength*.

Sound waves are not just pressure waves

When a sound wave propagates, it affects the density, pressure, and particle velocity of the fluid particles. The impact on the density occurs because as molecules are compressed together, the local density (ρ) will increase and in regions of rarefraction the density will decrease. For an acoustic wave it is convenient to write the total density as:

$$\rho = \rho_0 + \rho_a \qquad \text{(Eq 49.2)}$$

where ρ_0 is the ambient density of the medium (in the absence of sound) and ρ_a is the variation in the density due to the acoustic wave.

The pressure in the fluid can similarly be written as the sum of two terms:

$$p = p_0 + p_a \qquad \text{(Eq 49.3)}$$

where p_0 is the ambient pressure (in the absence of sound) and p_a, the *acoustic pressure*, is the fluctuation due to the sound wave. For most fluids, acoustic pressure and density are directly related by an "equation of state" which takes the form:

$$p_a = \rho_a\, c_0^{\,2} \qquad \text{(Eq 49.4)}$$

That is, where the wave is compressed the pressure will be positive and where the fluid is rarefied the pressure will be negative. Physically, pressure represents a force per unit area and has units of Pascals (Pa). One Pascal is quite a small pressure and atmospheric pressure at sea level is approximately 100 000 Pa. In biomedical ultrasound, acoustic pressure is normally measured in megaPascals (MPa).

By way of example, the amplitude of the pressure from a diagnostic ultrasound scanner is about 2 MPa at the focus. Typically, values for ρ_0 and c_0 in tissue are 1000 kg/m^3 and 1540 m/s, respectively, and so this corresponds to a relative density perturbation of $\rho_a/\rho_0 = 0.0009$. For lithotripsy, peak pressures can be upwards of 100 MPa, which results in $\rho_a/\rho_0 = 0.04$. Therefore, the density disturbances associated with acoustic waves in medical devices, even the very strong waves that are produced in lithotripsy, actually result in very weak (<5%) compression of the fluid.

Progressive waves and particle velocity

The case shown in Figure 49.3 where the compression wave moves in one direction is referred to as a *progressive wave*. In contrast, when there are sound waves traveling in different directions, this is referred to as a *compound wave*, which will not be considered here. For a progressive wave the molecules in the compressed region also have a small net velocity away from the source. The net velocity of the molecules in a region of space is referred to as the *particle velocity* (u_a) and for a progressive acoustic wave it can be expressed as:

$$u_a = p_a / \rho_0\, c_0 \qquad \text{(Eq 49.5)}$$

Using the example of a 100-MPa shock wave, the instantaneous particle velocity at the peak is about 67 m/s. It will be shown below that the particle velocity is needed in order to determine the energy in an acoustic wave.

If the velocity is integrated in time, the displacement of tissue can be calculated. For the 100-MPa shock wave described above, the tissue will move about 30 μm during the 1 μs compressive phase and then slowly return to its original position during the tensile phase. It has also been suggested that the particle velocity within a biologic target may produce sufficient strain to damage the cells. Below it will be discussed how the deformation can also build up over many pulses and in certain cases may damage tissue.

Acoustic impedance

The density and sound speed of a material (Eq 49.4) determine its *specific acoustic impedance* ($Z_0 = \rho_0\, c_0$). This term is often shortened to *acoustic impedance* or just *impedance*. The impedance of tissue and water is about 1.5×10^6 kg/m^2/s. The units are often referred to as Rayls, after the eminent 19th century acoustician Lord Rayleigh, although the Rayl is not a standard SI unit.

Therefore, for a progressive acoustic wave, the pressure, density and particle velocity are not independent but are linearly related to each other:

$$p_a = u_a Z_0 = \rho_a c_0^2 \quad \text{(Eq 49.6)}$$

where the coefficients are material properties. It follows that regions of high pressure are also compressed and have a high particle velocity (away from source), and regions of low pressure are rarefied and have a negative particle velocity (towards the source). As the acoustic wave travels, the fluctuations in density, pressure, and particle velocity all move together (i.e. "in phase"). Therefore, in a fluid with known material properties, if one property of an acoustic wave, such as the acoustic pressure, is measured, then Eq 49.5 can be used to determine the other acoustic properties.

Wave intensity or energy

A propagating acoustic wave carries energy. The amount of acoustic energy per unit area is called the *energy flux*, *energy density*, *energy flux density*, or the *pulse intensity integral*. An IEC standard, which describes how pressure measurements should be taken on a lithotripter to ensure accurate results and fair comparisons across devices, defines the energy per unit area the "pulse intensity integral (energy density)" (PII) [20]. It can be calculated from the following integral:

$$PII = \int p_a u_a dt \quad \text{(Eq 49.7)}$$

where the integration is done over the duration of the pulse. This is the acoustic equivalent to the expression from physics "work equals force times distance," where acoustic pressure is the force per unit area and the time integral of the velocity gives the distance. The units for PII are joules per square meter (J/m^2). For a progressive wave it is known that the particle velocity is related to the acoustic pressure $u_a = p_a/Z_0$ and therefore:

$$PII = \int \frac{p_a^2}{Z_0} dt \quad \text{(Eq 49.8)}$$

in which case the pressure of the wave needs to be measured to determine PII. Note that to calculate the integral, the entire pressure versus time waveform needs to be accurately measured so that the integration can be done.

To determine the energy in an acoustic wave, a specific area A has to be chosen and the energy that passes through that area can then be calculated as:

$$E = \iint PII dA \quad \text{(Eq 49.9)}$$

where the double integral indicates a surface integral over the area A. The units for energy are Joules (J). The energy E will depend on both the size of the area A and how the intensity varies across the area. The *focal acoustic pulse energy* is calculated using the area in the focal plane where the pressure is greater than half the maximum pressure (this is equivalent to the *focal zone*, see below). Various other conventions have been employed to calculate energy in SWL, e.g. the projected area of a stone or the area where the peak pressure is above 5 MPa [21].

Another acoustic property is the power per unit area or the *intensity* (I). Power is energy per unit time and so the intensity is the energy density divided by the time over which the integration was done (Eq 49.8), which is normally the pulse length (T_p):

$$I = \frac{PII}{T_p} \quad \text{(Eq 49.10)}$$

Intensity has units of watts per square meter (W/m^2) but it is more common in biomedical ultrasound to use W/cm^2.

For a sinusoidal pressure wave the integral (Eq 49.8) can be calculated exactly and the intensity is:

$$I = \frac{\hat{p}^2}{2Z_0} \quad \text{(Eq 49.11)}$$

where $\hat{p}$ is the peak pressure of the sinusoidal wave. If the impedance for water or tissue (Z_0 = 1.5 MRayls) is substituted, the relationship can be expressed as $\hat{p} = \sqrt{3I}$ where $\hat{p}$ is in atmospheres of pressure and I is in W/cm^2. For pulsed pressure waves, such as in lithotripsy, a simple expression does not exist for the intensity, as even small changes in the pulse shape can have a significant effect on the integration used to calculate *PII*.

Reflection and transmission of sound waves

When an acoustic wave encounters a medium with a different impedance, then part of the wave will continue to propagate into the new medium (the transmitted wave) and part of the wave will be reflected back into the original medium (the reflected wave). In the case of *normal incidence*, where the propagation direction of the shock wave is perpendicular to the surface, the amplitude of the transmitted and reflected waves depends only on the change in impedance between the two media, what is referred to as the *impedance mismatch*. In terms of acoustic pressure the transmission and reflection coefficients are:

$$R_p = \frac{Z_2 - Z_1}{Z_2 + Z_1} \quad \text{(Eq 49.12)}$$

$$T_p = \frac{2Z_2}{Z_2 + Z_1} \quad \text{(Eq 49.13)}$$

There are a different set of coefficients for the intensity or energy, which are called the intensity transmission and reflection coefficients:

$$R_I = \frac{(Z_2 - Z_1)^2}{(Z_2 + Z_1)^2} = R_p^2 \quad \text{(Eq 49.14)}$$

$$T_I = \frac{4Z_1Z_2}{(Z_2 + Z_1)^2} = 1 - R_I \quad \text{(Eq 49.15)}$$

Figure 49.4 shows the intensity transmission coefficient for an acoustic wave going from water to another medium with different impedance. The typical values for tissue, kidney stones, bone, and air are indicated. It can be seen that the transmission from water to tissue is very efficient. The water–stone transmission is also relatively high, with 75–95% of the energy being transmitted into kidney stones. However, a water–air interface has an extremely small coefficient and less than 0.1% of the energy of an acoustic wave in water will pass into air, i.e. 99.9% is reflected. This is why shock-wave generators in lithotripsy are water filled, why immersion of the patient in water gives the most efficient coupling of shock waves to the body, and why in dry lithotripters great care must be taken to eliminate air pockets between the shock head and the body [22, 23]. This is also one reason why stones are not targeted for treatment through lung or segments of gas-filled bowel. Indeed, the best *acoustic window*, which allows the shock wave a pure tissue path to the kidney, is on the flank of the patient (delineated by the ribs, spine. and pelvic bone).

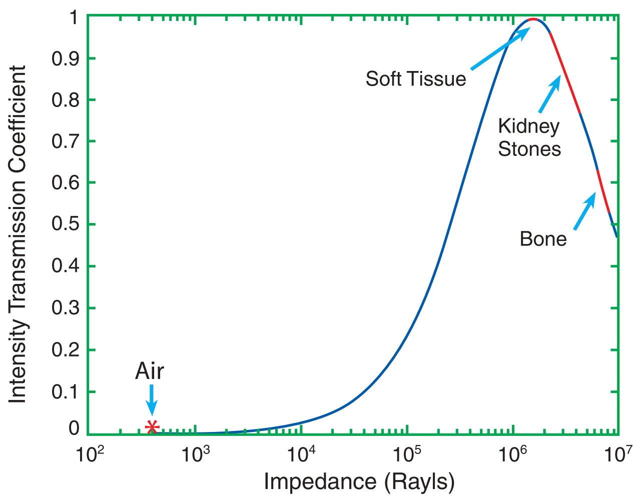

Figure 49.4 Intensity transmission coefficient (TI) from water ($Z = 1.5 \times 10^6$ Rayls) to a second medium, as a function of the impedance of the second medium. Typical values are indicated for soft tissue, kidney stones, bone, and air. The transmission to soft tissue is very efficient. Coupling to air is very poor.

Focusing and diffraction of sound

In lithotripsy, focusing of the shock waves is used to concentrate the acoustic energy on to the stone, while reducing the impact on the surrounding tissue as much as possible. Lithotripters achieve focusing by various means, including the use of reflectors, acoustic lenses, and spherically curved sources. Regardless of the method used, the physics that describes the focusing of the waves is similar for all these cases. An ideal focus would be the case where all energy is localized to an infinitesimally small region in space. However, the physics of wave propagation does not allow the energy to be focused to an arbitrarily small volume due to a process called *diffraction*. This means that even though the acoustic pressure may be greatest at one point in space, there is a finite region or volume of surrounding space that is also at high amplitude. This called the *focal zone*. For a theoretically optimal focusing arrangement, where sound can come in from all angles, diffraction puts a limit on the size of the focal zone of about one wavelength. For the realistic focusing arrangements used in lithotripsy, where the sound only comes from one direction, the focal zone can be from a few millimeters to tens of millimeters in size.

Focal zone

The *focal zone* of a lithotripter (equivalent terms include *focal region*, *hot spot*, *focal spot*, *focal volume*, *zone of high pressure*) of a lithotripter is normally ellipsoidal in shape with its longest dimension along the axis of the shock wave. To demonstrate this, Figure 49.5 shows the predicted peak pressure of the focal zone in an unmodified Dornier HM3 lithotripter [24]. The length and diameter

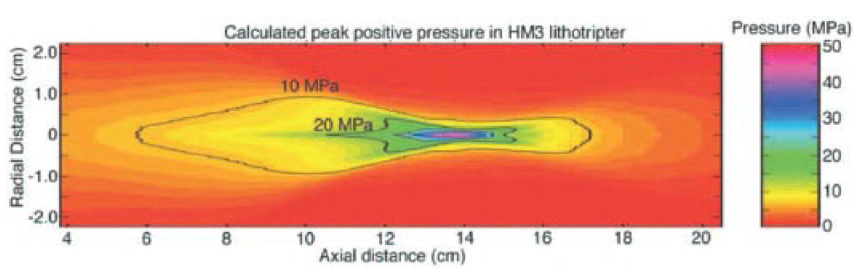

Figure 49.5 Calculated spatial distribution of the peak positive pressure for the Dornier HM3 lithotripter. The focal volume can be determined by determining the zone where the pressure is at least half the maximum pressure.

of the focal zone depends on the diameter of the source, the focal length of the source, and the frequency content of the waveform. The dimension of the focal zone is, thus, one characteristic of any given lithotripter that is determined by design features and, as will be discussed below, focal zones can vary greatly between lithotripters.

For a focused acoustic source that generates a sinusoidal waveform, such as an ultrasound transducer, there are analytical expressions for the size of the focal zone. The critical parameters are the wavelength of the sound wave (λ) and the half angle of the aperture:

$$\alpha = \arcsin(D/2F). \qquad \text{(Eq 49.16)}$$

where D is the diameter of the source and F the *focal length*. The formulae for the length (L_{FZ}) and the diameter (D_{FZ}) of the focal zone are:

$$L_{FZ} = \frac{0.6\lambda}{\sin^2(\alpha/2)} \qquad \text{(Eq 49.17)}$$

$$D_{FZ} = \frac{0.7\lambda}{\sin\alpha} \qquad \text{(Eq 49.18)}$$

Note that the focal length (F) is the distance from the mouth of the therapy head to the focus (where the stone should be placed). The focal length should not be confused with the length of the focal zone (L_{FZ}), which is the region around the focus where the pressure is high.

For a pulsed waveform, as is generated in lithotripsy, there are no explicit formulae for the size of the focal volume as the size depends on the waveform shape. However, the focal region of a lithotripter can be estimated using the formulae for the focal region of a sine wave. Figure 49.6A shows how the focal zone gets shorter and narrower as the diameter of the source aperture is increased. Figure 49.6B shows how the focal zone gets shorter and narrower as the focal length of the source (source–target distance) is decreased. Therefore, to make a small focal zone, a shock source with a large diameter aperture and short focal length would be desired. However, the size of the acoustic window in the flank and the need to be able to target stones deep in the body mean that for most lithotripters both the focal length and the diameter of the aperture are around 15 cm.

Nonlinear acoustics

When an acoustic wave has very large amplitude, e.g. a lithotripter shock wave, the speed of the wave is no longer constant but depends on the local compression of the fluid. For "weak" shock waves (recall even at the focus of the highest power lithotripter, the water is compressed by < 5%), the speed of propagation ("phase speed") of an acoustic wave is:

$$c_{phase} = c_0 + \beta p_a / \rho_o\, c_0 \qquad \text{(Eq 49.19)}$$

where β is the *coefficient of nonlinearity* of the fluid and is a material property of the medium. For water β is about 3.5 and for tissue it varies from about 4 to 9. Normally, tissue of more complex structure has a greater coefficient of nonlinearity. A reasonable value for healthy soft tissue is 5.

Nonlinearity arises because of two physical processes; first, in regions of high pressure the local sound speed is increased above the usual value, and second the molecules in regions of high pressure have a higher particle velocity and are convected in the direction of acoustic propagation. For sound traveling through tissue, it is the first process that dominates the nonlinearity.

The difference between a nonlinear wave and a linear wave is that for a nonlinear wave, different parts of the wave travel at different speeds, as described by Eq 49.19. Figure 49.7 shows what happens to a sinusoidal wave as it propagates with nonlinearity present. The waveform becomes distorted in shape. In the absence of absorption, the wave obtains an infinite slope and then folds over and becomes multivalued. Ocean waves fanning up the beach are such waves but this waveform is not physically realizable in acoustics, i.e. it is not possible to have more than one pressure at any one point in space.

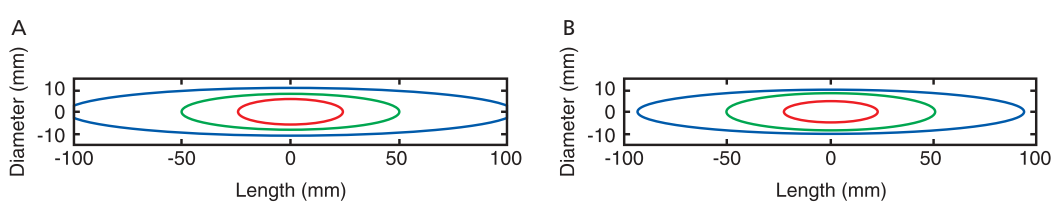

Figure 49.6 Predicted focal zone size as a function of the diameter of the source and the focal length of the source for a 500 kHz source. (A) Contours show size of the focal zone for a source that has a focal length of 14 cm and an aperture of 25 cm (red), 15 cm (green), and 10 cm (blue). The focal zone gets longer and wider as the aperture size decreases. (B) Contours show the size of the focal zone for a source with fixed aperture diameter (15 cm) and varying focal length: 8 cm (red), 14 cm (green), and 20 cm (blue). The focal zone gets broader and longer as the focal length increases. For reference the Dornier HM3 hemi-ellipsoidal reflector has a focal length of 13 cm and an aperture diameter of 15 cm.

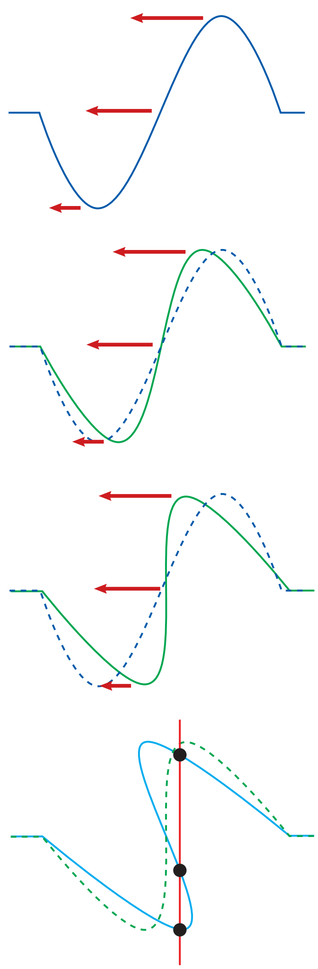

Figure 49.7 Nonlinear distortion of a sine wave based on Eq 49.19. (A) Initial waveform; the length of the arrows shows the local phase speed of different points on the waveform. The peak will move the fastest and the trough the slowest. (B) Waveform after a short amount of propagation (dashed line is waveform in A) showing how the shape has distorted. (C) Shock formation distance where the slope of the waveform first becomes infinite (dashed line is waveform in A). (D) Predicted multi-valued waveform; the vertical line indicates that there are three different pressures predicted at one point in time (dashed line is from C). This shape is nonphysical as absorption will prevent the wave from folding over.

Shock formation

The point at which the waveform first attains an infinite slope is called the *shock formation distance*. For a sinusoidal waveform this distance is:

$$\bar{x} = \frac{\rho_0 c_0^3}{\beta \hat{p} 2\pi f} \qquad \text{(Eq 49.20)}$$

Any acoustic wave can result in a shock wave if it can propagate for a long enough distance. However, for most sound waves encountered in everyday life, the shock formation distance is so long that the wave has been absorbed before it can form a shock.

Rise time

In acoustics, waveforms are prevented from folding over (or breaking) by the presence of acoustic loss mechanisms. All acoustic waves will leave behind a small fraction of their energy as they propagate through a fluid; this loss of energy is referred to as *absorption* and will be discussed in the next section. The absorption of sound is greater from waveforms with steep gradients. In the case of a shock wave where the slope tends towards infinity, the absorption will also tend towards infinity. The shock will, therefore, never attain an infinite slope, but instead a balance between nonlinear distortion and absorption will result in a shock front where the pressure jumps in a very short time. This time is referred to as the *rise time* of the shock or the Taylor shock thickness. For a shock wave in water the expression for the Taylor shock thickness is:

$$T_{rt} = \frac{5}{\Delta P}\,\mathrm{ns}\cdot\mathrm{MPa} \qquad \text{(Eq 49.21)}$$

where ΔP is the pressure jump in MPa and the rise time (in ns) is defined as the time to go from 10% to 90% of ΔP. From this expression it is found that a 1-MPa shock should have a rise time of 5 ns and a 10-MPa shock a rise time of 0.5 ns. As a shock becomes stronger, the rise time shortens. Using Eq 49.1, the corresponding spatial extent of the rise time of the 1- and 10-MPa shock waves is 7.5 µm and 0.75 µm, respectively.

Nonlinear acoustics phenomena are also important in other areas of biomedical ultrasound. In diagnostic ultrasound, nonlinear effects can create problems such as excess heating of tissue [25, 26], but can also be beneficial by enhancing image quality in tissue harmonic imaging [27–29]. Nonlinear effects are also important in high intensity focused ultrasound surgery (HIFU or FUS), where ultrasonic heating of tissue is exploited to destroy specific regions of tissue or to coagulate blood [30–33].

Absorption of sound by tissue

As mentioned above, when a sound wave passes through a medium, most of the energy remains in the sound wave but a small amount of it is absorbed by the medium. The amplitude of an acoustic wave will therefore slowly decay or *attenuate* as it propagates through a medium. The absorption in water is very low and, aside from controlling the rise time of the shock front, has little effect on lithotripter waveforms. The absorption in tissue, however, is about 1000 times larger than that in water and has a measurable effect on lithotripter

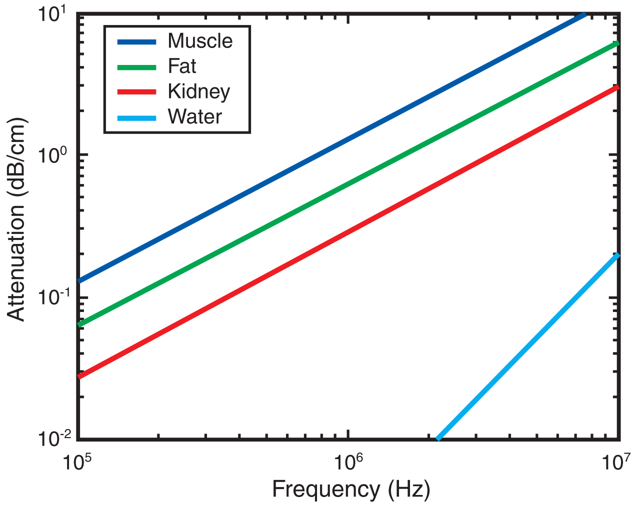

Figure 49.8 Attenuation of sound as a function of frequency for muscle, fat, and kidney tissue (listed in decreasing order of loss). Also shown is the attenuation in water, which is much less (1000 times at 1 MHz) than the attenuation of tissue.

shock waves as they pass through the body and into the kidney. Typical values for absorption in muscle, fat, and kidney are shown in Figure 49.8 as a function of frequency. It can be seen that the absorption increases (almost linearly) with frequency. This means that energy is removed more effectively from the higher frequencies of the sound wave. In lithotripsy waveforms, the high frequency components are associated with the shock front. The primary action of tissue absorption is to increase the rise time of the shock front, and this will also result in the peak amplitude being reduced. The main energy components of the wave (which are around 300 kHz) will not be significantly impacted by tissue attenuation, and therefore the basic shape of the pulse is not be affected by propagation through tissue and the peak negative pressure in particular is not sensitive to tissue absorption.

How shock waves are measured

Hydrophones

The main physical property of a lithotripter is the spatial and temporal distribution of its acoustic pressure field. The acoustic field is typically measured in water using a hydrophone, which converts pressure into an electrical signal. Lithotripters generate short (wide frequency band), high amplitude acoustic pulses, which are focused to a small volume in space. These physical parameters require that the hydrophone needs to be: (1) of a very wide bandwidth (60 kHz to in excess of 20 MHz); (2) robust enough to withstand the high pressures of the shock waves; and (3) possess a small active area (~0.5 mm). The first reliable measurements of lithotripsy shock waves were performed with a hydrophone made of polyvinyl difluoride (PVDF), a piezoelectric plastic [34]. PVDF has very wide bandwidth, is capable of measuring high amplitude acoustic pressures, and can be manufactured so that only a small region is active. Both membrane hydrophones and needle hydrophones have been used, however membrane hydrophones are considered to yield the best measurement of the shock wave [35]. One problem with PVDF is that its adhesion with water is not strong and the tensile phase of the lithotripsy pulse can result in cavitation at the surface of the PVDF. This is a significant limitation that has two main consequences. First, it limits the ability of the hydrophone to measure the tensile phase of the shock wave as once the bubble forms the negative pressure is relieved and the hydrophone registers a pressure close to zero. Second, when the cavitation bubbles collapse, they can irreversibly damage the hydrophone.

The fiberoptic probe hydrophone (FOPH) [36] is considered to be the state of the art for measuring lithotripsy shock waves, and is the recommended device in the IEC standard [20]. The FOPH consists of a laser that injects light into one end of an optical fiber; the other end of the fiber is placed in the lithotripter field. The FOPH measures the light that is reflected from the end of the fiber and exploits the fact that the amplitude of the reflection depends on the pressure in the fluid. Several features make the FOPH superior to the PVDF membrane. Similar to PVDF, the FOPH has a wide bandwidth and is capable of measuring very high pressure amplitudes. The diameter of the active area of the FOPH (100 μm) is smaller than most PVDF hydrophones (500 μm). Also, the FOPH is made of an optical fiber (silica) and the adhesion between water and silica is very high. This means that cavitation is much less likely to occur at the surface of the FOPH and therefore it can more accurately capture the tensile phase of the shock wave. This also means that the FOPH is less susceptible to damage from cavitation. The main drawback with the FOPH is that the signal it generates is weak and therefore it is not good for measuring low pressures (~2 MPa and less).

Measuring shock waves in the body

All published measures of dimensions of the focal zone come from *in vitro* experiments and there have been few attempts to collect any shock-wave pressure data in animals. Both the high attenuation and inhomogeneous nature of tissue will affect shock waves as they propagate through the body. Figure 49.9 shows representative pressure waveforms for a Dornier HM3 measured in water and for a PVDF membrane hydrophone implanted in a pig [37]. The *in vivo* waveform is very similar in

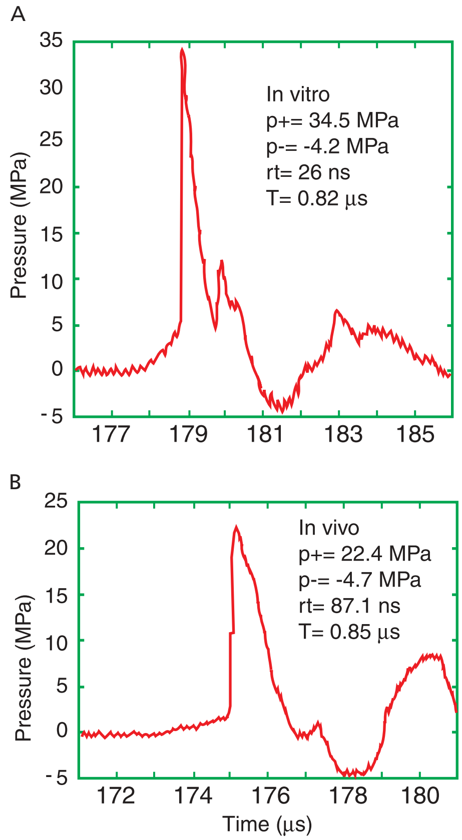

Figure 49.9 (A) Waveform measured in water with a miniature polyvinyl difluoride (PVDF) hydrophone in a Dornier HM3 at 18 kV. (B) Waveform measured *in vivo* in a pig for the same settings. The peak amplitude *in vivo* was about 30% less than that in water, and the rise time *in vivo* (78 ns) was much longer than that measured in water (26 ns).

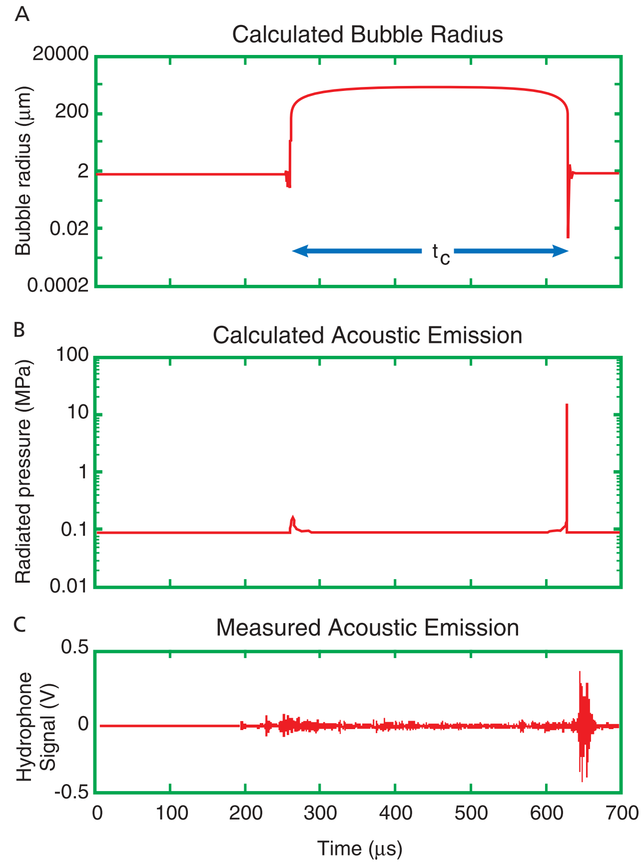

Figure 49.10 (A) Calculated radius versus time curve of a spherical bubble subjected to a lithotripter pulse (as in Figure 49.1). In this time scale the shock wave arrives at the focus at 250 μs and the bubble is initially crushed by the leading compressive phase. The bubble grows to a millimeter at about 450 μs. It then starts to collapse with a violent collapse occurring at 650 μs. The time between the two collapse signals is the characteristic time (t_C). (B) Predicted acoustic emissions that the bubble calculated in A will radiate. There are two emissions due to the two collapses. (C) Measured acoustic emissions in a Dornier HM3 using a passive cavitation detection (PCD) (see Figure 49.11). The measured emissions agree with the calculations.

basic shape to the *in vitro* waveform. The main difference is that the *in vivo* waveform has a 30% decrease in peak positive pressure and a greatly increased shock rise time (~70 ns). Both of these effects are consistent with the higher attenuation associated with tissue and the heterogeneity of the tissue in the path to the kidney.

Acoustic cavitation

What is acoustic cavitation?

A second mechanical force generated by lithotripter shock waves is *acoustic cavitation*. This refers to the generation of cavities in a fluid (i.e. bubbles) when the tensile phase (negative pressure) of the acoustic wave is sufficiently strong to rip the fluid apart. In lithotripsy the tensile phase of the shock wave is large enough (~10 MPa) to generate violent cavitation events. Cavitation is believed to play a significant role in tissue damage during SWL and to contribute to stone comminution [38–44].

Typically, cavitation is initiated at micron size motes in the fluid or at sites of small gas pockets trapped on rough surfaces [45]. There are a number of different theories [46, 47] that can describe how acoustic cavitation proceeds once the cavity has been formed (at this point the cavity is normally referred to as a bubble). In Figure 49.10 the predicted radius is shown of a spherical bubble as a function of time in response to a lithotripter shock wave. The bubble is first compressed by the positive phase of the shock wave. Then the tensile phase of the shock wave causes the bubble to grow from 1 μm radius to about 1 mm radius over a period of 150 μs. Note that the bubble continues to grow long after the shock wave has passed (5 μs time frame),

referred to as inertial cavitation, as the dynamics of the bubble are no longer driven by acoustics but instead by the inertia of the fluid surrounding the bubble. While the bubble is large, some amount of gas and vapor from the fluid will diffuse into the bubble. The bubble will then collapse by virtue of the near vacuum inside the bubble and the roughly 1 atm of ambient pressure in the surrounding fluid. It takes a further 150 μs for the bubble to collapse. The collapse is very violent and the gas that diffused inside is heated and compressed to such an extent that it can produce light [48]. The main collapse is followed by rebounds after which the gas that had diffused into the bubble will slowly diffuse back out into the fluid. Also shown in Figure 49.10 is the acoustic emission radiated by the bubble; a lithotripsy-induced cavitation bubble generates two acoustic emissions, one when it is hit by the compressive wave and one when it collapses hundreds of microseconds later. This unique "double-bang" signature can be used to detect the cavitation events [48].

Measuring cavitation

There are numerous techniques by which cavitation can be measured:

High-speed photography

Bubble behavior can be observed using a high-speed camera in an *in vitro* setting [49–52]. In principle this allows the entire dynamics of a bubble to be tracked from genesis to extinction, but in practice this is not feasible. During the growth phase the bubble needs to be imaged at millimeter length scales and tens of microsecond time scales. At the nadir of the collapse, the bubble radius is less than 1 μm and the dynamics of the collapse is at nanosecond time scales. The remnant bubble left after the rebounds is of the order of 10 μm and slowly dissolves over hundreds of milliseconds. Thus, the range of temporal and spatial scales makes it virtually impossible to capture all the bubble dynamics photographically. Therefore, investigators have found it necessary to study cavitation in segments. A further limitation of imaging is that cameras have a limited depth of field and cannot give an adequate record of bubble dynamics throughout the substantial volume of the cavitation field.

Laser scattering of single bubbles

The dynamics of a single spherical bubble can be measured very precisely by laser scattering [53]. In this case, a laser beam is used to illuminate a bubble and a photodetector is used to collect the light scattered by the bubble. For a spherical bubble, the amplitude of the scattered light varies in a known way as the bubble radius changes. This method is able to capture most of the temporal and spatial scales associated with the dynamics of a lithotripsy-excited cavitation bubble. However, laser scattering has several restrictions; the sample volume is very small, the method requires unrestricted visual access at high magnification, and the theory that is used to recover the actual bubble size is based on a single spherical bubble. This means the technique will only yield qualitative information about bubble clouds or nonspherical bubbles, both of which are very common in lithotripsy-induced cavitation.

Acoustic detection **in vivo**

Acoustic detection of bubbles is very powerful, in part because it can be used to characterize bubble dynamics within living subjects. Acoustic detection normally works in one of two modes: active cavitation detection (ACD) and passive cavitation detection (PCD) [54–56]. In ACD one transducer is used to send an acoustic wave toward the cavitation field, while a second transducer picks up sound reflections from the bubbles; this is the acoustic analog to laser scattering. In PCD, one or more receiving transducers listen for the "double-bang" acoustic emissions from cavitation bubbles (Figure 49.11). In the case where two receiving transducers (dual PCD) are used, it is possible to take advantage of coincidence detection to sample a small, discrete volume of the cavitation field where the transducers intersect [57]. The timing and amplitude of the two emissions is influenced by various factors such as the size of the initial bubble and the amplitude of the lithotripter pulse.

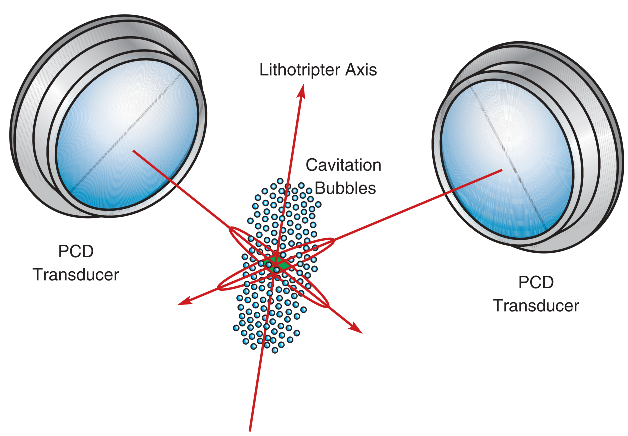

Figure 49.11 Dual passive cavitation detection system. Two focused transducers are placed so that their ellipsoidal focal zones intersect. Acoustic emissions that occur in the shaded region of intersection can be localized by searching for simultaneous events on both transducers.

Thus, although acoustic detection does not image bubbles (i.e. it cannot provide information on bubble number and size), it gives valuable data that can be used to help characterize the acoustic output of a lithotripter and assess the environment and dynamics of the cavitation field [51, 57, 58].

Other techniques have also been developed for measuring cavitation. It has been observed that cavitation leads to pitting on metal foils and the number and depth of pits can be used to assess the violence of cavitation [38, 59, 60]. An electromagnetic probe device has been used to measure the mechanical force exerted on a steel ball by both the incident shock wave and the cavitation activity [61]. The high pressures and temperatures in the interior of the bubble provide an environment which can produce light emissions (sonoluminescence) and also result in enhanced chemical reaction rates (sonochemistry). Production of light and by-products from chemical reactions have both been used to quantify cavitation activity [53, 58]. These are secondary measurements of the cavitation field and interpreting the results in terms of physical processes can be complicated.

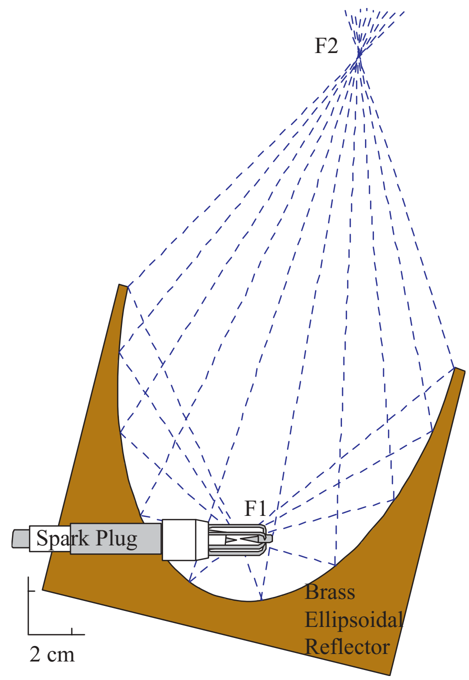

Figure 49.12 Focusing design of a Dornier HM3 electrohydraulic lithotripter. A spark plug is located at the focus (F1) of an ellipsoidal reflector. Energy from the spark plug is reflected and focused to the second focus of the ellipsoidal reflector (F2).

Physics of clinical lithotripsy

Shock generation and focusing

Three shock-wave generating principles have been used in clinical lithotripters.

Electrohydraulic lithotripters

The electrohydraulic lithotripter (EHL) has a spark source which generates a shock wave that is focused by an ellipsoidal reflector (Figure 49.12). In an EHL the pressure pulse originates as a shock wave and remains a shock wave at all times during its propagation from the spark source to the reflector, and then as it focuses to the target. As will be shown below, this is not the case for other types of shock-wave sources. In an EHL, focusing of the shock wave is critically dependent on the placement of the spark at the first focus of the ellipse. Misalignment by just a few millimeters can lead to a significant loss in focusing, and a lengthening and broadening of the focal zone. Thus, EHLs are designed so that the alignment of the electrode is consistent. Still, there is variability in the precise location of the spark discharge across the spark gap that is not easy to control. Therefore, from shot-to-shot there can be significant variation (upwards of 50%) in the amplitude of the shock wave and there can be some shift in the position of the focal zone at the target. A unique “feature” of EHLs is that the target is insonified by two pulses. The main focused pulse is preceded by the so-called “direct wave,” which travels directly from the spark to the target without bouncing off the reflector. The direct wave arrives about 30 μs earlier and, because it undergoes spherical spreading, it is low in amplitude. However, it has been shown that this direct wave can influence the cavitation generated by the focused wave [62].

In EHL the electrodes wear out and must be replaced. Some lithotripter manufacturers have found ways to enhance the lifetime of their electrodes, such as by encapsulating them and filling the casing with an appropriate electrolyte [63]. Still, electrodes eventually show wear and this can affect their acoustic output.

Electromagnetic lithotripters

The electromagnetic lithotripter (EML) uses an electrical coil in close proximity to a metal plate as an acoustic source. When the coil is excited by a short electrical pulse, the plate experiences a repulsive force and this is used to generate an acoustic wave. If the metal plate is flat, the resulting acoustic wave is a plane wave that must then be focused by an acoustic lens (Figure 49.13A). If the plate is in the shape of a tube, the resulting cylindrical wave can be focused by a parabolic reflector (Figure 49.13B). In both cases, focusing is very reproducible and variation in measured pressure waves is less than 10%. Thus, the shock waves generated by EMLs are

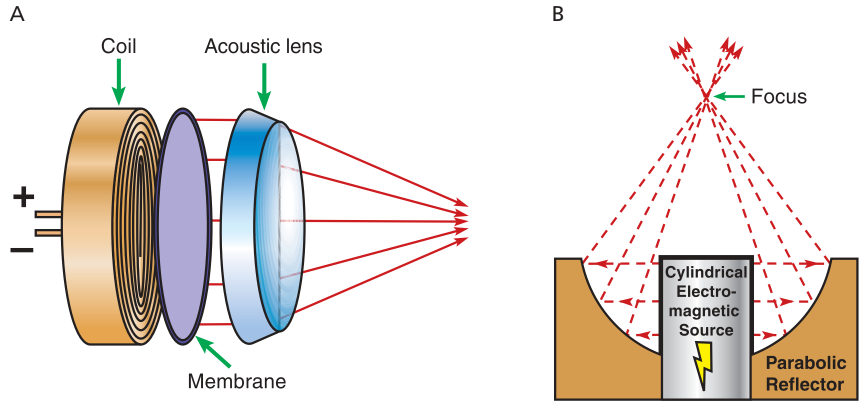

Figure 49.13 The two focusing mechanisms employed in electromagnetic lithotripters. (A) In a Siemens lithotripter, a membrane is driven by a coil to produce a plane wave, which is then focused by an acoustic lens. (B) In a Storz lithotripter, a coil excites a cylindrical membrane, which generates a wave that is focused by a parabolic reflector.

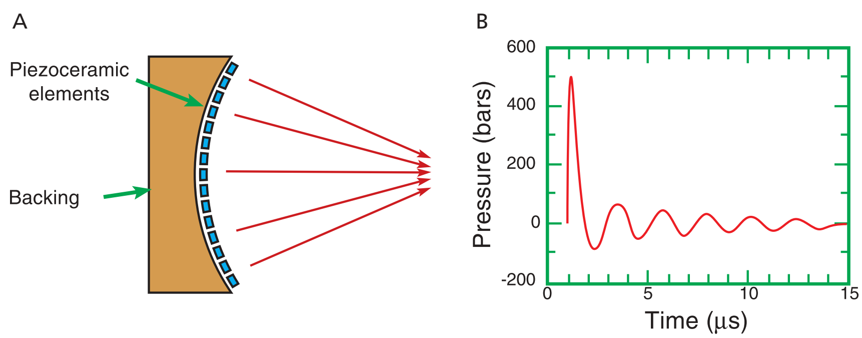

Figure 49.14 (A) Fundamental principles for a piezoelectric lithotripter. Piezoceramic elements are placed onto the surface of a sphere. The wave will focus to the center of the radius of curvature of that sphere. (B) Typical waveform measured at the focus of a piezoelectric lithotripter. Note the long ringdown for time greater than 3 μs.

inherently more consistent than in EHLs. An additional advantage is that there are no electrodes to replace.

One difference between the acoustics of an EML and an EHL is that the acoustic pulse generated by an EML does not start as a shock wave; the displacement of the plate generates a high-intensity ultrasonic wave, which has a smooth waveform with no discontinuities. The amplitude of the wave at clinically relevant power settings is normally high enough that nonlinear distortion occurs during propagation, and a shock is produced before the wave reaches the focus. One exception is a broad focal zone EML which does not produce a shock at the focus [64]. A second difference is that the EML waveforms have a relatively small trailing positive pressure after the negative phase (this can be observed at about 6 μs in Figure 49.2). This peak likely has little impact on the stress inside the stone but may affect the cavitation dynamics.

Piezoelectric lithotripter

The piezoelectric lithotripter (PEL) uses piezoelectric crystals to form an ultrasonic wave. When a voltage is applied to a piezoelectric crystal, it deforms and creates an acoustic wave. The crystals are placed on the inside of a spherical cap and the acoustic wave focuses at the centre of curvature of the sphere (Figure 49.14A). This focus is highly reproducible and very small variations in the focal waveforms are reported. Similar to the EML, the acoustic waveform in PEL starts as an acoustic pulse and a shock wave is created by nonlinear propagation distortion. For most clinical settings a shock is produced before the wave reaches the focus. Figure 49.14B shows a representative waveform from a PEL [65]. One significant difference from an EHL or EML waveform is the presence of a tail or coda at the end of the pulse. This is because the piezoelectric crystals "ring" for a couple of cycles after they are excited, a phenomenon not present in an EHL or EML. The coda at the end of the PEL pulse probably has a minimal effect on the stress induced in a kidney stone but may affect the cavitation dynamics.

Coupling of the shock source to the body

Efficient transfer of acoustic energy from one medium to another only occurs when the acoustic impedances

are very close. A water–tissue interface results in very good coupling and theoretically it should be possible to transfer more than 99% of the energy of the shock wave into the body. However, the presence of even a small pocket of air at the skin surface will result in a dramatic reduction in energy transfer to the patient (see Figure 49.4). Thus, the manner in which the shock wave is coupled to the body is critical.

Water-bath lithotripters

The "first-generation" lithotripters (e.g. Dornier HM3) were EHLs and used an open water bath in which the patient was immersed. Thus, there is nothing but water between the shock source and the patient. This is ideal except that bubbles that drift up from the spark gap or the cavitation bubbles that form along the path of the shock wave, have the potential to collect against the skin of the patient and interfere with the propagation of subsequent shock waves. To help prevent this, the ellipsoidal reflector of the shock source is fixed off vertical (in the Dornier HM3 the angle is 14°) and the water in the bath is continuously degassed.

Dry lithotripters

Most current lithotripters have the shock-wave source mounted in a "therapy head" which is filled with water. The therapy head is capped by a thin rubber membrane, which is pressed against the patient and through which the shock wave passes. The water in the therapy head of most lithotripters is continuously recirculated and degassed to remove any bubbles that might interfere with the shock-wave propagation. Although this design is more convenient in the clinic than a water-bath-type lithotripter, it is inherently less effective at allowing shock waves to pass because the presence of the rubber (although well matched to water and tissue) adds additional reflecting interfaces. A coupling agent such as gel or oil is used to marry the rubber membrane of the treatment head to the skin [66]. Although seemingly simple, this procedure may spell success or failure for treatment. Laboratory studies have shown the coupling interface to be prone to developing voids and such defects covering just 10% of the interface can reduce the breakage efficiency of model stones by around 60% [23]. The typical methods used to apply gel, such as dispensing from a squeeze bottle and rubbing by hand across the skin and treatment head, create defects and are highly variable. An improved method for coupling has been described [22].

Focal zone of the lithotripter

In lithotripsy, acoustic energy is focused to a relatively small focal zone surrounding the focal point of the lithotripter. The *focal point* is a geometric point in space, e.g. in an EHL this point is the second focal point (F2) of the ellipsoidal reflector [24], and it is usually the location at which the stone is placed for treatment. All lithotripters have a focal point, but lithotripters differ in the dimensions of the zone of high pressure (*focal zone)* that surrounds this point. The dimensions and the pressure characteristics of the focal zone are the most important features that distinguish one lithotripter from another.

There are many definitions of the focal zone that may be appropriate for lithotripsy. The IEC standard for measuring lithotripter pulses [20] defines it as the volume within which the measured peak acoustic pressure is at least half the maximum peak positive pressure. The peak positive pressure (p+) of a waveform (see Figure 49.1) is the highest positive pressure in that waveform. The maximum peak positive pressure is the highest value of p+ in the field of the lithotripter and the location of the maximum peak positive pressure is defined as the focus [20]. The maximum peak pressure will vary with the power setting of the machine. The resulting focal zone is normally an elongated, elliptical, "cigar-shaped" volume. It is worth noting that maximum peak pressure does not necessarily occur at the same location as where the manufacturer indicates a stone should be placed, and that the location of the focus and the dimensions of the focal zone may change as the power setting is changed.

The Dornier HM3 has arguably been studied and characterized more extensively than any other lithotripter. As such, data for the Dornier HM3 are a useful standard for reference. Because different lithotripters, even the same type of lithotripter, may perform somewhat differently, and because investigators have used different means to map the acoustic field of their lithotripters, published values for peak pressures and dimensions of the focal zone of a given type of lithotripter may not coincide perfectly. Representative focal zones of selected lithotripters are shown in Figure 49.15. Typical published values for the Dornier HM3 EHL report the maximum peak positive pressure to be 40 MPa at 20 kV and the focal zone to be about 60 mm long by 12 mm in diameter. In contrast the Storz Modulith EML has a maximum peak positive pressure around 100 MPa at energy level 8 and a focal zone that is about 35 mm long and only 4 mm in diameter. Reported values for PELs indicate a maximum peak positive pressure of 80 MPa and a focal zone 20 mm long and 3 mm in diameter [67, 68]. Thus, there is a considerable difference in the dimensions of the focal zone between lithotripters and those lithotripters with the narrowest focal zone have the highest peak pressures.

The half-maximum focal zone (also known as –6 dB focal zone as the contour corresponds to the pressure being 6 dB less than at the maximum) is recommended

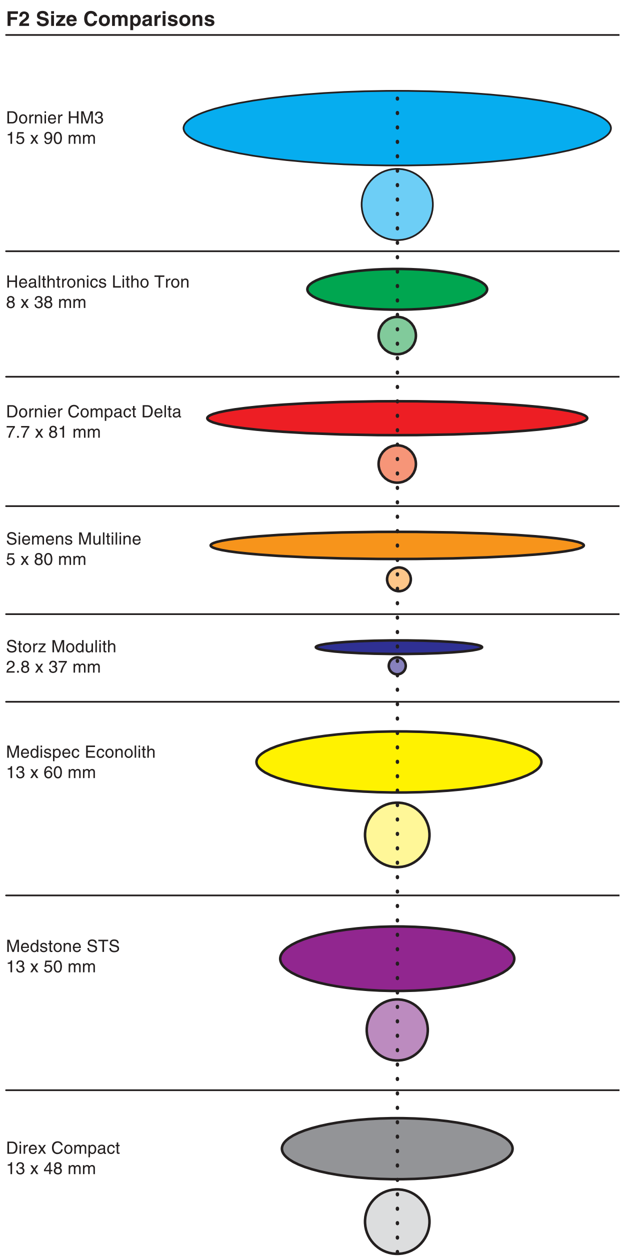

Figure 49.15 Comparison of the focal zones of selected clinical lithotripters showing their dimension along the axis of the lithotripter (ellipses) and in the focal plane at the focus (circles) (image courtesy of P. Blomgren).

in the IEC standard, but this may not necessarily be the best descriptor of the focal zone of a lithotripter. For example, in a Storz lithotripter, with a peak pressure of 110 MPa at energy level 9, the focal zone will correspond to the region where the peak pressure exceeds 55 MPa. For a Dornier HM3, which only has a peak pressure of 40 MPa, the focal zone will correspond to a region where the pressure exceeds 20 MPa. Therefore, when comparing the focal zones of these machines the absolute pressure levels are very different; indeed, the focal zone of a Dornier HM3 would be zero if the 55 MPa level of the Storz focal zone were used. Other suggestions for the focal zone include: half the peak negative pressure, half the energy density, the surface where the peak pressure is 5 MPa, or even using the energy that passes through a volume with a diameter of 10 mm (about the size of a typical stone). Until there is a better understanding of how shock waves fragment stones, it is unlikely that an alternative metric will be agreed upon within the literature.

The smaller, tighter focal spot of an EML or PEL would at first glance appear to be advantageous as it should allow for more accurate targeting on the stone, and thus, less damage to the surrounding tissue. However, *in vitro* experiments (where stones are stationary) indicate that the EMLs or PELs, with their very high pressures, are no better at breaking stones that an EHL and often are not as effective [69, 70]. High peak positive pressure does not appear to correlate with enhanced stone fragmentation in the clinic [4, 15, 16].

Further, stone motion due to respiration means that with a tight focal zone fewer shock waves actually hit the stone and more shock-wave energy is deposited directly into tissue [71]. When it is considered that some tight focal zone lithotripters have peak pressures in excess of 100 MPa, this suggests that tissue is being subjected to a very high dose of acoustic energy. This may help explain the increased incidence of adverse effects such as subcapsular hematomas observed with these machines [6, 13].

Device equivalency/equating lithotripter performance

At present there are no agreed metrics by which the acoustic output of different lithtotripters can be compared, and there is no straightforward means to operate a given lithotripter so that it is equivalent to another. This is partly due to the fact that, although all lithotripters produce shock waves that have similar waveforms, the amplitude and focal zone of different lithotripters is not the same, and measurements of the properties of the acoustic field can yield very different values. This is illustrated in Table 49.1, where a number of physical measurements made on an EHL and an EML are shown [72]. For the settings chosen, the only parameter that was roughly equivalent was the energy incident on a 6.5-mm diameter stone (0.484 mJ vs 0.528 mJ). However, other physical measurements varied tremendously, e.g. the peak positive pressure in the EML was three times that of the EHL.

Therefore, although it is possible to find settings on two given machines that give equivalency on one physical property, it is unlikely that there will be equivalency on other properties and, indeed, there is likely to be significant differences. For example, if the power setting

Table 49.1 Comparison of physical properties measured in an electrohydraulic lithotripter (EHL) and an electromagnetic lithotripter (EML) [53]. The columns show measurements of the length and width of the focal zone, the peak pressures (p+ and p–), the energy in the focal zone (E_{FZ}) (Eq 49.9 using the area given by width of the focal zone), the energy incident on a stone (E_{STONE}) (Eq 49.9 using the area with diameter of the stone 6.5 mm), and the characteristic time of cavitation, which is a measure of the strength of cavitation. The bottom row shows the ratio of the values in the EHL to the EML. For the settings used here, the energy delivered to the stone was the one quantitative parameter that was approximately equivalent.

	$Length_{FZ}$	$Width_{FZ}$	p+	p–	E_{FZ}	E_{STONE}	t_C
EHL	54 mm	9 mm	37.5 MPa	–7.8 MPa	4.25 mJ	0.484 mJ	250 μs
EML	32 mm	3.5 mm	115 MPa	–14.6 MPa	3.35 mJ	0.528 mJ	350 μs
Ratio	1.69	2.57	0.33	0.53	1.27	0.92	0.71

were to be reduced on the EML to yield the same pressure as the EHL, then the energy measurements would drop by almost a factor of 10.

A further confounding issue is the number of shock waves to be used. The clinical literature suggests that typically fewer shock waves are required to break stones on an EHL in comparison to an EML. In addition, the rate at which shock waves are delivered has also been reported to affect fragmentation efficiency [73]. Therefore, at the current time there is no clear way in which the three main parameters of shock-wave delivery for a lithotripter (power, number of shock waves, and rate of shock-wave delivery) can be adjusted to ensure equivalency between different machines.

Mechanisms of shock-wave action

Acoustic waves in stones

A number of mechanisms have been proposed by which lithotripsy shock waves may destroy kidney stones. The acoustic field in stones is more complex than the acoustic theory described for shock waves in tissue. Kidney stones are elastic solids and support two types of waves: a longitudinal or compression wave (which is akin to an acoustic wave) and transverse or shear waves, where the motion of the vibration is transverse to the direction of propagation. In a shear wave, the transverse vibration does not result in the molecules being compressed and rarefied, but rather they oscillate in a manner analogous to the wave motion of a rope excited by a snap of the wrist. Longitudinal waves and shear waves travel at different speed and the longitudinal wave speed (c_L) is always faster than the transverse wave speed (c_T).

When a shock wave passes from urine or tissue into a stone, the transmitted energy is divided between the longitudinal and transverse waves in the stone. How the shock-wave energy is divided between the longitudinal and transverse waves depends on the material properties of the stone and the angle of incidence. If the wave is normally incident on the stone surface, then all the energy is converted into a longitudinal wave in the stone and no energy is available for transverse waves. As the angle of incidence increases, less energy is converted into a longitudinal wave and more is converted into transverse waves. The complex shape of many natural stones results in a nontrivial partition of energy between the two types of wave.

The basic features of the interaction of shock waves with a stone can be illustrated by means of a computer simulation. The computer simulation solves the equations of motion for particles in an elastic solid [17]. Figure 49.16 shows a series of snap-shots of the interaction of a lithotripter shock wave with a cylinder-shaped stone. The snap-shots show the distribution of the maximum tensile stress inside the stone at each instant of time. In the first two frames, the shock wave can be seen to enter the stone as compressional waves. The third and fourth frames show that the longitudinal wave inside the stone and the acoustic wave outside the stone result in the generation of shear waves from the lateral walls. Further, between the third and fourth frames, the shock wave reflects from the rear wall. Because the impedance of the surrounding fluid is less than that of the stone, the reflected pressure wave is inverted (because the pressure reflection coefficient R_P given in Eq 49.19 is negative if $Z_2 < Z_1$) and the leading compressive wave is reflected as a tensile wave. The last two frames show constructive interference between the shear and longitudinal waves to produce the high tensile stresses in the stone.

Acoustic properties of stones

From the point of view of determining the stress inside a kidney stone, the important material properties are: density (ρ_0), longitudinal sound speed (c_L), and shear wave velocity (c_T). Figure 49.17 shows reported measurements from human stones [74–77]. There is a large variation in the reported properties for uric acid, calcium oxalate monohydrate, and cystine stones, e.g. the sound speed in calcium oxalate monohydrate varies between 3000 m/s and 4500 m/s. This variation is likely due to

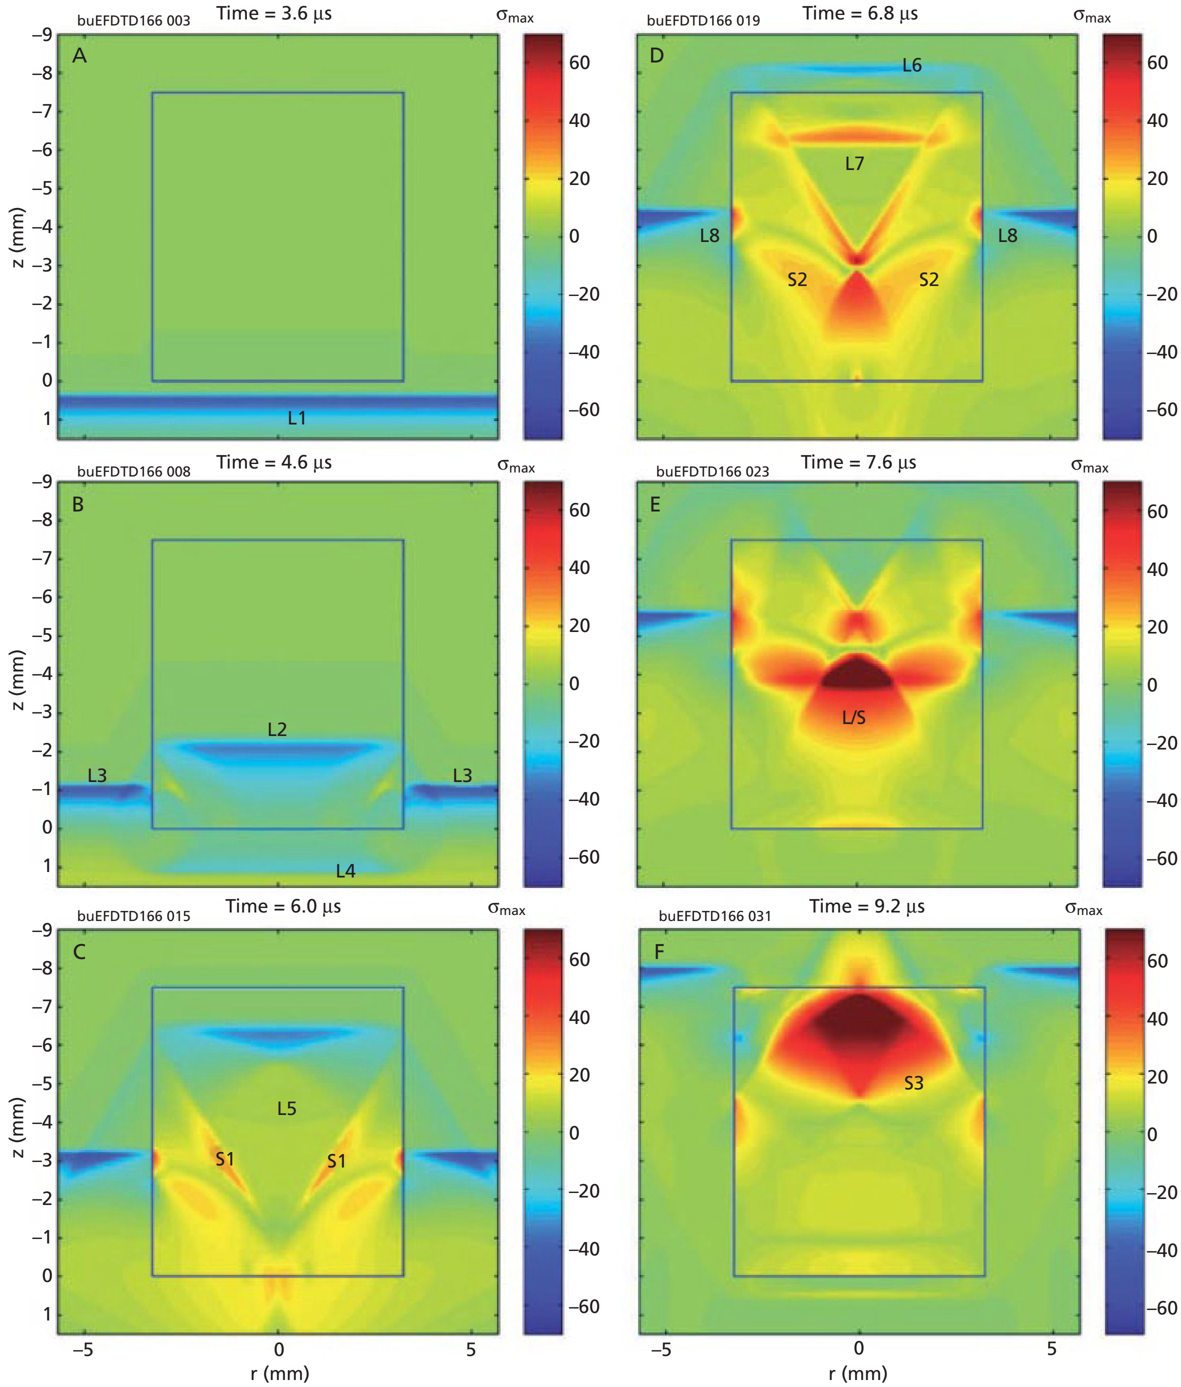

Figure 49.16 Snap-shots of the tensile stress generated by the propagation of a lithotripsy shock wave through a model kidney stone surrounded by fluid. The cylindrical stone (6.5 mm wide × 7.5 mm high) has the following properties $\rho = 1700\,\mathrm{kg/m^3}$, $c_L = 3000\,\mathrm{m/s}$, $c_S = 1500\,\mathrm{m/s}$. The shock wave is incident from below and the color scale depicts the tensile stress (in MPa), where yellow through red indicate regions of tensile stress, and blue regions of compression. (A) (at 3.6 μs) The leading compressional phase of the shock wave in the fluid (L1) is almost incident on the proximal surface of the stone. (B) (4.6 μs) The shock wave has entered the stone as a longitudinal wave (L2). Note because the propagation axis is normal to the surface, no shear waves are generated at this interface. Because the speed in the stone is higher than in the fluid, the wave in the stone advances ahead of the wave in the fluid (L3). The reflection of the shock wave by the proximal surface can be seen leaving the bottom of the image (L4). (C) (6.0 μs) The tensile tail of the incident shock wave can be seen in the stone (L5) following the leading compressive phase. The interaction of the longitudinal wave in the stone with the lateral walls of the stone results in the production of shear waves (S1) that propagate towards the axis of the stone. (D) (6.8 μs) The leading compressive phase has been partially transmitted (L6) and reflected (L7) at the distal surface. The reflection coefficient is approximately −0.5 and results in a tensile phase (L7) that generates significant tensile stress (red region) near the distal surface; this is spall. The wave on the outside of the stone (L8) is inducing further shear waves (S2) inside the stone. (E) (7.6 μs) The reflected longitudinal wave and the shear waves interact to produce a large region of tensile stress in the center of the stone (L/S). (F) (9.2 μs) The shear waves interact near the distal surface to generate another region of high tensile stress (S3).

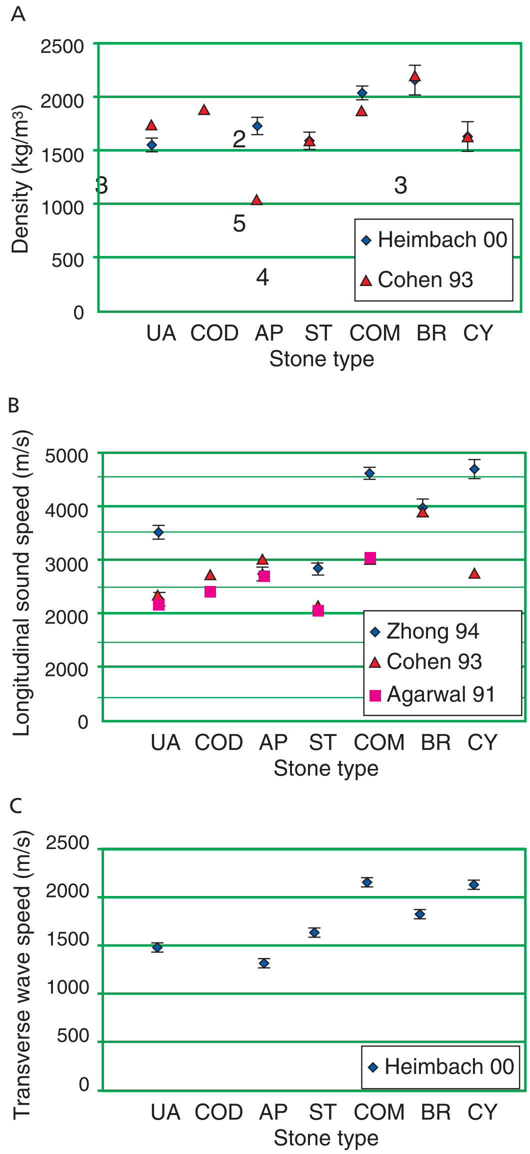

Figure 49.17 Reported measurements of acoustic properties in human stones [74–77]. (A) Density, (B) sound speed, (C) shear wave speed. UA, uric acid; COD, calcium oxalate dihydrate; AP, apatite; ST, struvite; COM, calcium oxalate monohydrate; BR, brushite; CY, cystine.

the natural variation in the properties of the stones, but may also be related to the preparation of the stones (e.g. amount of hydration).

How shock waves break stones

Numerous mechanisms by which shock waves may fragment stones have been described in the literature. It is likely that some combination of these mechanisms plays a role in the actual fragmentation process. Here, we give a synopsis of some of the most likely mechanisms (Figure 49.18).

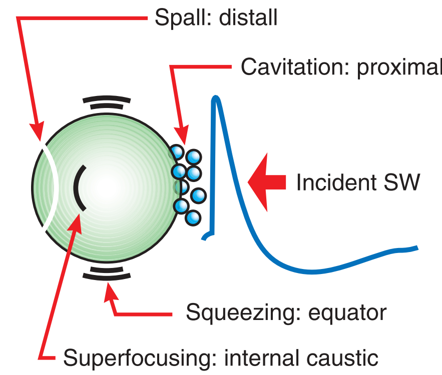

Figure 49.18 Regions where different stone fracture mechanisms will act.

Spall fracture

Spallation occurs after the shock wave enters the stone and subsequently reflects from the rear of the stone (see Figure 49.16). The stone–urine interface inverts the large positive pressure pulse, resulting in a large tensile stress. This stress is added to the tensile stress of the, still incoming, negative pressure tail, resulting in a very large tensile stress near the back wall [78–81]. Most solids are much weaker in tension than in compression, so the large tensile stress near the rear of the stone can be expected to make the material fail. Recent fundamental research suggests that spall plays a small role in the fragmentation of kidney stones [17, 19]

Squeezing

Squeezing occurs because of the difference in sound speed between the stone (>2500 m/s) and the surrounding fluid (~1500 m/s). The shock wave inside the stone "runs away" from the shock wave propagating through the fluid outside of the stone (see Figure 49.16B,C). The shock wave that propagates in the fluid outside the stone results in a circumferential force on the stone (known as a hoop stress). It has been proposed that this will result in a tensile stress at the proximal and distal ends of the stone and lead to an axial "splitting" failure [82]. More recent dynamic studies suggest that squeezing produces shear waves that then produce high tensile stresses internal to the stone towards the distal surface [17]. It is these regions of high tension associated with shear waves that appear to correlate best with *in vitro* stone fragmentation [19].

Shear stress

The shear waves and compressive waves that propagate inside a kidney stone (see Figure 49.16) will generate regions of high shear stress in the stone. Figure 49.19 shows *in vitro* experiments in which regions of high

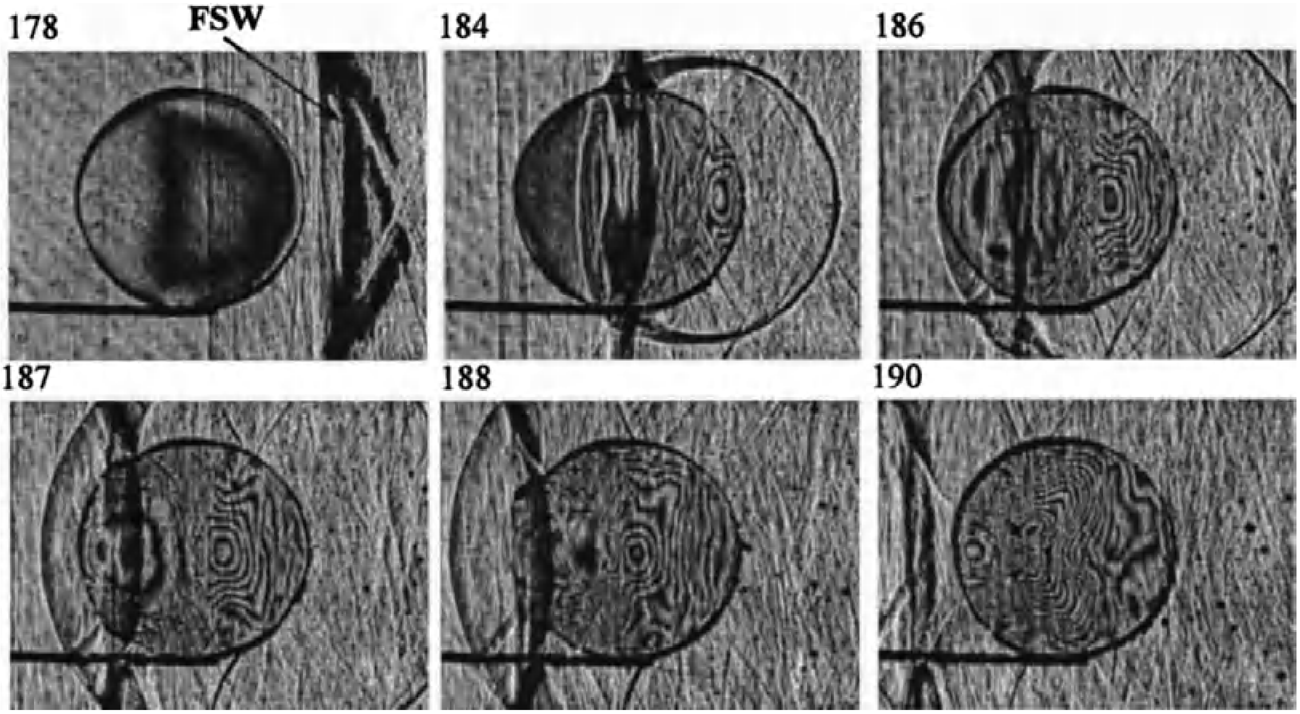

Figure 49.19 Stress waves in cylindrical stone (14-mm diameter) which was subject to a shock wave (moving from right to left) for a Dornier HM3. At 178 μs the shock wave is almost incident on the stone. At 184 μs the shock wave has entered the stone and has also reflected. At 186 μs the compressive phase of the shock wave has just made it to the distal surface of the stone and a shear wave can be seen at the mid point of the stone. At 187 μs the compressive wave has exited the stone and the shear wave is focused along the axis of the stone. At 188 μs the shear wave reaches the distal surface of the stone. At 190 μs the shock wave has passed by the stone and there is still reverberation inside the stone. (Reproduced from Xi and Zhong [84], with permission. Copyright © 2011 Acoustical Society of America).

shear in a stone can be visualized. Many materials are weak in shear, particularly those that have layers. In the case of kidney stones that consist of layers, the bonding strength of the matrix between the layers often has a low ultimate shear stress [78, 79, 83, 84]. Further, the organic binder of kidney stones is much softer than the crystalline phase, and as the shock front passes through the stone, it will induce very large shear stresses at the binder–crystal interfaces which likely contribute to the fracture of the kidney stone [85].

Superfocusing

Superfocusing is the amplification of stresses inside the stone due to the geometry of the stone. The shock wave that is reflected at the distal surface of the stone can be focused either by refraction (associated with the high sound speed and geometry of the stone) or by diffraction from the corners of the stone. It has been shown that these reflected waves can be focused to caustics (regions of high stress) in the interior of the stone and that this can lead to failure [84, 86]. The regions of high stress (both tensile and shear) can be determined from the geometry of the stone and its elastic properties, e.g. density, longitudinal wave speed, and shear wave speed.

Cavitation

Cavitation refers to small bubbles/cavities that grow in the urine surrounding the stone in response to the large negative pressure tail of the acoustic pulse. When a cavitation bubble collapses near a solid surface (e.g. a kidney stone), a microjet of fluid is formed that pierces the bubble and impacts the surface (Figure 49.20) with speeds upwards of 100 m/s [39]. This jet likely plays a role in cavitation-induced damage to kidney stones [39–40]. The collapse of the cavitation bubble also results in the emissions of secondary shock waves [87, 88] that are radiated into the stone. These secondary shock waves have an amplitude comparable to that of the focused shock wave [89].

In vitro experiments where cavitation is suppressed show significant reduction in stone fragmentation [59, 90, 91]. Cavitation is principally a surface-acting mechanism, and experiments indicate that it acts most strongly on the proximal (shock-wave incident) surface of the stone [40, 80, 92]. Studies suggest that cavitation is

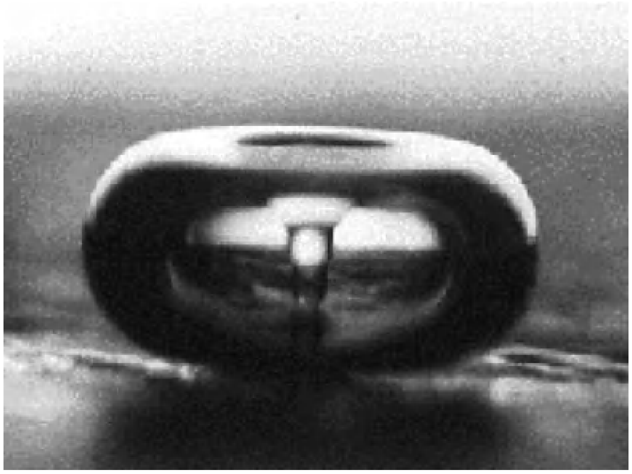

Figure 49.20 Cavitation bubble collapsing on a metal surface [27]. A jet of fluid can be seen punching through the center of the bubble toward the metal surface (courtesy of Dr L. A. Crum).

perhaps most effective once stones have been broken into fragments less than 3–4 mm in diameter [93], as this is a size where direct stress effects are less important and cavitation has more surface area to act upon.

It has also been suggested that the stresses imparted by cavitation can act by a spall mechanism [86, 94]. Also it has been recognized that the cavitation generated by lithotripters acts as a cluster of bubbles (Figure 49.21) rather than individual bubbles, and that the coherent collapse of the cluster may enhance the destructive power of cavitation [52, 95, 96].

Fatigue

Fatigue is a process that may occur anywhere in the stone. Its hallmark is the progressive development of cracks [97–98]. The cracks are nucleated at sites of small imperfections that occur in almost all materials; these nucleation sites will be present in all kidney stones. The imperfections are sites of "stress concentrations" which, when a shock wave passes, can lead to local stresses far in excess of the average stress induced by the shock wave [99]. These very high stresses can cause the imperfections to grow into micro-cracks with the passage of a number of shock waves. With subsequent shock waves, the micro-cracks grow into macro-cracks and eventually produce cracks large enough to induce failure. The cracks can be grown either by large tensile stresses or by large shear stresses. Therefore, fatigue will be enhanced wherever regions of high stress coincide with weak points in the stone. This means that there could be a synergistic effect between fatigue and some of the other mechanisms that result in localized regions of high tensile or shear stress. There are two pieces of evidence that strongly support the argument that stone comminution is a fatigue process. First, the internal structure of stones has been shown to affect how they fragment in lithotripsy [100–103]. Second, normally more than 1000 shock waves are required to progressively fragment stones into sufficiently small pieces; the use of multiple stress cycles to fracture a material is a classic hallmark of fatigue [97, 98].

Although, present understanding of SWL indicates that the stones fail through a fatigue process, it is not clear which mechanism drives the fatigue. The two most commonly cited mechanisms are direct stresses (tension and shear) and cavitation, or some combination of them [93]. Part of the problem in determining which mechanism is in action is that only limited data on the material strength of kidney stones has been reported, e.g. ultimate strength in compression, fracture toughness, Knoop hardness, and Vickers micro-hardness [74–76, 104–107]. Of note is the paucity of data for the tensile and shear strength of kidney stones. This is most likely because determining these properties in brittle materials is fraught with technical difficulties. Further, most of the data have been measured in quasi-static tests, with the stress applied over many minutes, and the results may not be representative of the material properties when subject to shock waves, where the stress is applied and removed in microseconds [85]. At present the data on material strength of kidney stones are insufficient for the fracture process to be described.

Mechanisms of tissue damage

It is now well recognized that SWL results in trauma to the kidney, and that in some cases the injury can be severe [9]. The clinical implications of such adverse effects are still under investigation and a thorough discussion of the complications associated with lithotripsy is given in Chapter 53.

The notion that lithotripter shock waves can pass harmlessly through the body is simply not true. It is likely that all patients who receive at least an average dose of shock waves (2000 shock waves at mid-range power or higher) experience some degree of tissue trauma. Lithotripsy has been very beneficial for a large number of patients, but it has also led to severe, even catastrophic adverse effects for others [9, 11, 108]. To better understand how shock waves have the potential to cause tissue trauma, the physics of the problem needs to be considered.

As discussed above, lithotripters produce a focused acoustic pulse. The acoustic field is broad at the source and narrow at the focus. The focal zone, the area of highest acoustic pressure, is elongated and of dimensions that cannot be localized exclusively to a stone.

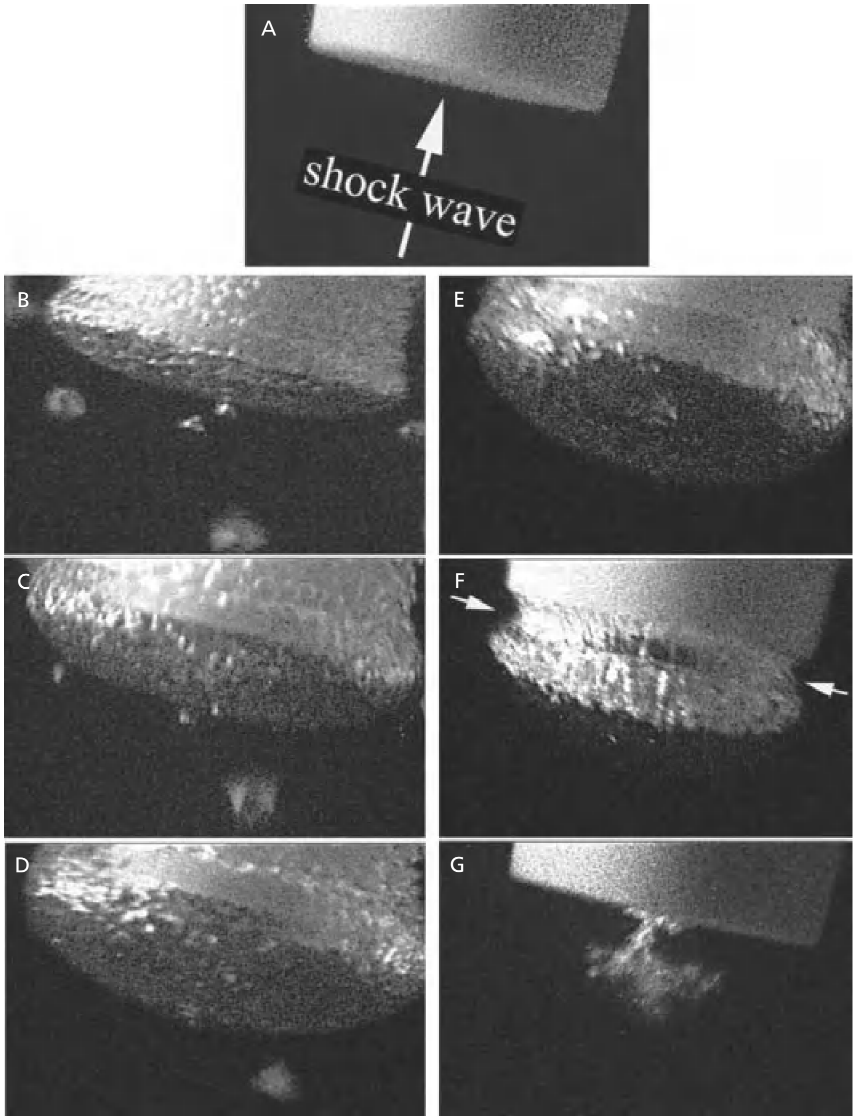

Figure 49.21 Cavitation bubble cluster collapse on a stone 6.5 mm in diameter × 7.5-mm long. (A) Orientation of shock wave to stone. (B) 100 μs after shock-wave arrival a bubble cluster has formed on the proximal surface and a few bubbles have formed in the surrounding fluid. (C–-E) (200, 300 and 400 μs after shock-wave arrival, respectively) the cluster continues to grow. (F) The cluster begins to collapse in a mushroom-like shape. (G) Final collapse of the cluster at the centre of the stone (reproduced from Pishchalnikov *et al*. [52] with permission).

Although shock waves are targeted onto the stone, the surrounding tissue is also subject to significant mechanical forces. The length of the focal zone of most lithotripters is about 50 mm (see Figure 49.15) and this means that the entire thickness of the kidney is subject to high amplitude shock waves. In addition, patient motion, due to respiration or discomfort, likely results in the stone spending a good portion of the treatment time out of the focal region and, thus, many of the shock waves will interact solely with tissue.

Fortunately, tissue has physical properties that make it far less susceptible to damage by shock waves than kidney stones. For example, the fact that the acoustic impedance of tissue is close to that of water means that shock waves can pass through a tissue–water interface without significant reflection. Thus, tissue is not subjected to the extreme tensile forces that cause stones to fail. Further, the sound speed in tissue is almost constant and so tissue will not be subject to squeezing, which can generate tensile and shear stresses. However, tissue is subject to deformation by the pressure wave and to cavitation induced by the tensile phase of the shock wave. We briefly describe the mechanisms that maybe contribute to tissue injury.

Mechanical stress

The positive pressure of a lithotripter pulse leads to significant compression of tissue. The fact that the shock rise time *in vivo* is of the order of 70 ns means that the spatial extent of the shock front is about 100 µm. Therefore, tissue structures in the range of 10 µm to 1 mm will experience a significant variation in stress across them as the shock wave passes. The short rise time associated with the shock will lead to nonuniform straining of the tissue, resulting in shear forces. It is generally recognized that tissue structures are sensitive to shear stress and the distortion of the tissue by the shock wave could induce enough shear to cause damage [109, 110].

Cumulative shear

As mentioned above, the positive phase of the shock wave can induce a displacement in tissue of tens of microns. The tissue returns to its original state during the negative phase. However, there can be a small net displacement remaining in the tissue after the passage of the shock wave. Eventually the elasticity of the tissue will relax the tissue back to its state. However, for kidney tissue it has been estimated that this time scale may be of the order of 1 s [111]. This means that for shock waves that are delivered at rates faster than 1 s, i.e. faster than 60 shock waves/min, the tissue will not have time to return to its rest state before the next shock wave is delivered. Over thousands of shock waves the net displacement could build up to sufficient levels to result in tearing of the tissue: a process referred to as cumulative shear [111].

Shear induced by inhomogeneities

Tissue is an inhomogeneous medium at multiple length scales. Spatial variation in the sound speed on the millimeter length scale can have a dramatic effect on the focusing of ultrasonic pulses in tissue [112]. As the shock wave focuses, parts of the wavefront that passed through tissue with high sound speed will be advanced and the parts that passed though low sound speed tissue will fall back. This distortion in the wavefront will lead directly to shear stresses in the tissue. Again, these shear stresses could be strong enough to induce mechanical damage of the tissue [109].

Cavitation

Cavitation is known to occur in tissue during lithotripsy [51, 113–115]. Measurements using passive cavitation detection in both humans and pigs have detected the unique acoustic signature associated with cavitation. Measurements have indicated the presence of cavitation in the perirenal fat, collecting system, parenchyma, and subcapsular hematomas.

Cavitation has been well documented to have a significant biologic effect in many *in vitro* settings [116–121]. Experiments in lithotripsy indicate that damage to *in vitro* cells and *in vivo* tissue is dramatically reduced when cavitation is reduced or eliminated [42, 121, 122]. This makes cavitation the most likely candidate for tissue damage in tissue. The onset of detectable cavitation in the parenchyma requires about 1000 shock waves to be delivered using a Dornier HM3 in the pig model [115]. This is consistent with the approximately 1000 shock-wave dose needed to observe widespread damage in the pig kidney for the same shock-wave settings [9]. These data suggest that in SWL widespread damage to the kidney can be attributed to cavitation.

For cavitation bubbles to undergo a violent growth and collapse cycle, the bubble needs to be in a fluid environment. This implies that cavitation activity, at least initially, is more likely to occur in the fluid environment of blood vessels than within the surrounding tissue. There are at least two mechanisms by which bubbles could produce mechanical damage to vessel walls and once a vessel is ruptured it is likely that cavitation activity progresses quickly.

Bubble expansion Bubbles may rupture vessel walls during the expansion phase of the bubble cycle. That is, as the negative pressure of the shock wave passes through the vessel it causes the bubble to undergo explosive growth (see Figure 49.10) pushing outward on the vessel and rupturing it. Experiments using cellulose tubes as capillary phantoms in an *in vitro* setting support the explosive bubble hypothesis [123, 124]. However, measurements of bubble activity in isolated mesentery vessels suggest that bubble growth results in little distention of vessel walls and that bubble collapse is more likely to result in injury for thin-walled vessels particularly, such as venules [125].

Bubble collapse When cavitation bubbles collapse near rigid surfaces they can form high-velocity microjets that are forceful enough to etch metal surfaces (Figure 49.20). These jets would also appear to be capable of puncturing the wall of a capillary or other blood vessel; however, bubble dynamics near elastically “soft” boundaries do not result in jetting towards the surface. High-speed movies of bubble activity in mesentery vessels found no evidence of jetting towards the wall [125]. Rather the dominant effect of the collapsing bubbles was to produce a focal invagination of the order of 10 µm, with deformation that has the potential to induce vessel rupture.

Cavitation progression Once blood vessels have been ruptured, either by mechanical stresses or cavitation bubbles inside intact vessel, blood will collect in pools, e.g. in a hematoma, and there is a greater potential for cavitation to occur. The pooling of blood provides a large fluid-filled space for cavitation bubbles to grow and collapse. Also, existing bubbles, which can act as nuclei for subsequent cavitation events, will not be swept away by blood flow, but will remain in the pooled region. This explains the intense PCD cavitation signals and B-scan ultrasound echogenicity collected from hematomas during SWL [113, 114, 126]. The ensuing violent cavitation could result in liquefaction of the tissue and the spread of a wave of cavitation-induced damage through the kidney [127].

Research continues in this area with the goal of confirming whether the physical processes outlined here, or some other processes, are responsible for tissue damage in SWL. This is partly due to the fact that the mechanical response of the tissue, at least at strain rates relevant in SWL, is not well understood, and so damage criteria are also not well defined. Further, there are few experimental systems that can be used to test and validate different hypotheses. Although the general consensus among researchers is that cavitation is the primary mechanism for tissue injury, this field still requires much study.

Evolution of the lithotripter

It is more than 30 years since the introduction of lithotripsy to clinical practice and there have been a number of noteworthy changes in equipment design, but none that has involved a fundamental change in the acoustics of the lithotripter. That is, lithotripters have changed (they are now compact, modular, use dry shock heads, have improved imaging), but the acoustic signature of the lithotripter pressure pulse remains the same. The focal waveform generated by a Dornier HM3 is virtually the same as the waveform produced by any of the numerous lithotripters available on the market today. This is not to imply that the lithotripter industry has been static. Indeed, there has been a very active effort on the part of manufacturers to produce machines that are easier and more practical to use. In this regard lithotripsy has seen numerous refinements. At the same time, however, it is essential to note that success rates in lithotripsy have declined [4, 15–16]. One refinement was to develop lithotripters that produced a tight focal zone of high peak positive pressure. However, as discussed above, data suggest that this led to decreased efficiency of stone breakage and to an increase in collateral damage. More recently, manufacturers have developed lithotripters with broader focal zones [128–130] or in the case of the Storz SLX-F2, a user-selectable focal zone. This is an example of progress in lithotripsy which comes at the expense of poorer outcomes and it appears that a step back is now being taken.

The first lithotripters were electrohydraulic devices in which the shock wave was generated by underwater spark discharge and shock-wave coupling was achieved by immersion of the patient in a water bath. The Dornier HM3 was a very popular lithotripter of this era, and at some centers is still in use today. By today's standards the Dornier HM3 produces moderate peak positive pressures (~40 MPa) delivered to a generous focal zone (~12×60 mm). The Dornier HM3 was a very successful machine and it is probably safe to say that the early success and rapid acceptance of lithotripsy was built on the back of this particular lithotripter.

Even though the Dornier HM3 was a very effective lithotripter, it was perceived by some to have several significant drawbacks. It used an open water bath to couple shock waves to the body; treatment was painful, necessitating that the patient be sedated or even anesthetized; the shock wave firing had to be gated to the cardiac cycle (to reduce risk of arrythmias), which slowed the treatment; and the lithotripter was a large, stationary piece of equipment that required a dedicated water treatment plant. What physicians (and patients) really wanted was lithotripsy that was painless, fast, and convenient with minimal to no anesthesia; a fully ambulatory walk-in-walk-out therapy. Lithotripter manufacturers responded with a number of modifications. Problems related to the overall physical design of the lithotripter were challenging but solvable. For example, the issue of the open water bath was addressed by enclosing the shock head and by using a rubber membrane to couple the shock wave to the body. This was not a perfect solution, as there is no better way to achieve acoustic coupling than through a water–tissue interface [23]. However, elimination of the water bath meant that medical staff had much easier access to the patient, the lithotripter did not necessarily have to be tied down to a dedicated facility, and lithotripters could be designed as modular systems. Many modern lithotripters have been designed to be portable and are used in mobile lithotripsy units.

The cardiac gating was found to be unnecessary for most patients and so most lithotripters run in "ungated" mode in which the urologist can chose the rate at which shock waves are delivered. Commonly, this will be at a rate of 2 Hz or 120 shock waves/min, which results in a much quicker treatment time. However, *in vitro* studies indicated that firing at higher rates resulted in worse stone fragmentation [131]. The likely explanation for this effect is that bubbles from a previous shock wave can last for many seconds [91] and that these bubbles can end up shielding the stone from the next shock wave [132]. The *in vitro* studies were followed up by animal studies which confirmed better stone comminution at

slower rates [73]. A number of clinical trials have reported data on the effect of rate and a meta-analysis of those studies indicates that firing at a lower rate does result in improved stone comminution [133]. Further data in the pig model indicate that delivering shock waves more slowly results in less tissue damage [64]. It may also be that at slower rates the cavitation bubbles from the previous shock have more time to dissipate and in addition cumulative shear should produce less damage [111].

The attempt to design a lithotripter so that it can be operated "anesthesia free," on the other hand, has proven to be a much more difficult problem. Discomfort during shock-wave treatment is due primarily to the sensation of cutaneous pain over the area of shock-wave entry at the surface of the body. One attempted solution was to widen the aperture at the shock source in order to spread the energy over a broader area. A wider aperture broadens the acoustic field along the shock-wave axis, but it narrows the focal zone of the pressure pulse. Many current lithotripters have a very narrow focal zone, of the order of 5 mm or less. Some of these lithotripters also generate huge peak positive pressures (in excess of 100 MPa). Because of respiratory motion, shooting at a stone using a narrow focal zone proves to be harder than when using a broad focal zone. Even if the shock wave could be kept directly on target, use of a narrow focal zone is less effective at delivering energy into the stone. Further, regardless of which lithotripter is used, lithotripsy is uncomfortable for the patient. If the patient is not sedated they will move to try to get more comfortable. Thus, attempts to build a totally anesthesia-free device have not yet been successful.

Another perceived disadvantage of the Dornier HM3 was the limited lifespan of the electrodes; it is necessary to replace the electrode one or more times during a treatment. EMLs and PELs do not use electrodes, which is an advantage in terms of cost, time, and convenience. In addition to the need to periodically change electrodes, electrode wear is an issue with EHLs. As the spark gap widens with use, there is increased variability in the path of the arc discharge. Also, as the spark gap widens, it takes higher a voltage to initiate a spark. Several manufacturers of current EHLs have found various ways to improve electrode life and some use designs such as encapsulation in an electrolyte-filled housing that extend the life of the electrode [17, 134].

Future directions in lithotripter design

More recent developments in lithotripsy could herald a positive change for the future of SWL. That is, there has been an effort to introduce novel approaches in lithotripter design that build upon well-tested theory and positive experimental results, targeting ways to improve stone breakage and reduce tissue injury. One approach is a response to the recent trend toward tight focal zone, high acoustic pressure machines. The Xi Xin-Eisenmenger lithotripter (Model CS-2012) is a wide-focus and low-pressure lithotripter that generates the largest focal zone (18 × 180 mm) and lowest range of acoustic pressures (10–25 MPa) currently in use in clinical practice [128]. This machine was developed to test the hypothesis that a very broad focal zone could be used to enhance stone breakage by circumferential squeezing [82]. It has been reported in an early trial that this machine delivers a high stone-free rate (86%) and can be used anesthesia free [128].

Cavitation control may be a means to improve lithotripsy. The cavitation bubble cycle, i.e. the time for a bubble to grow and then collapse, lasts of the order of 300 μs in the free field and ~600 μs at the surface of a stone [135]. Studies have shown that cavitation bubbles generated by one lithotripter pulse can be manipulated by a second pulse [136, 137]. If the second pulse arrives while bubbles are in their early growth phase, further expansion is stopped and the bubbles collapse with minimal damage. If, however, the second pulse arrives later in the cycle, bubble collapse is accelerated and damage is enhanced. Thus, the timing of the two pulses is critical. Bailey originated dual-pulse lithotripsy and in his studies used twin shock sources oriented coaxially facing one another [138]. Others have built upon this concept and have developed lithotripters that fire multiple pulses along the same axis [41, 139–140] or machines that use dual treatment heads offset at an angle to accommodate the constraints imposed by the anatomy of a patient [141–143]. At the current time, dual-pulse lithotripsy is under development and testing. The concept holds promise, as this may be a means to tailor acoustic forces within the focal zone for better breakage of stones, hopefully with reduced collateral damage [144, 145].

The safety of lithotripsy is a very important issue. Shock waves cause trauma and any strategy that lowers the dose of shock waves needed to treat a patient should be welcomed. One way to reduce unnecessary shock wave impact on tissue is to track the stone during treatment and to only fire when the shock wave will hit the stone. Devices have been proposed which monitor stone location and only allow shock waves to be fired when the stone is at the focus of the lithotripter [146–150]. A device has also been proposed to exploit acoustic time-reversal to dynamically change the focus of the lithotripter and so hit the stone even as it moves [151, 152]. Such concepts have the potential to dramatically reduce the number of shock waves required to break a stone. However, clinical devices do not currently employ real-time tracking.

Conclusions

SWL is a superb example of the successful transition of engineering technology into the clinical area. We have outlined the underlying acoustic principles that describe: the generation of the shock pulse, focusing, nonlinear distortion, coupling of the shock source to the body, and absorption of sound by the body. The exact mechanisms by which shock waves can damage stones and tissue are still not fully understood, although it is likely that direct stresses and cavitation are dominant in stone fragmentation and that cavitation is dominant in tissue injury. Improvements in lithotripsy, whether through improved use of existing lithotripters or through the development of new technologies, are likely to come only from an improved understanding of the acoustics and the physics of this problem.

In this chapter we have attempted to make the following main points:

- Most lithotripters produce a similar type of shock wave, which consists of a leading positive pressure shock front (compressive wave), lasting about 1 μs, followed by a negative pressure trough (tensile wave), which lasts about 3 μs. There is a large range in the amplitude of the shock waves used with peak positive pressures of 30–110 MPa, depending on the type of shock source and the power setting.
- Various types of shock-wave sources and focusing mechanisms have been exploited in lithotripsy. EMLs and EHLs dominate the lithotripsy market today.
- The size and dimensions of the focal zone are controlled by diffraction. Typically, EMLs have a smaller focal zone than EHLs and generate substantially higher peak positive pressures. A smaller focal zone is not necessarily an advantage as patient motion means that the stone can easily spend a significant amount of time outside the focal region. Currently, there is no good metric to determine equivalent action of different types of machines.
- Shock waves are coupled into the body using a water path that ideally is devoid of bubbles. Most current lithotripters use an enclosed water path in which the shock head is capped by a rubber membrane of low acoustic impedance. Such dry lithotripters tend not to be as efficient as the older water-bath lithotripters in which the patient is immersed in water during treatment. This reduced efficiency could be due at least in part to poorer coupling. Coupling can be improved by minimizing handling of the gel.
- The acoustic properties of tissue are very close to those of water, but tissue absorption and inhomogeneities lead to modest reduction of the peak positive pressure of the shock wave at the kidney. This is a significant finding for it validates *in vitro* experimentation as being representative of the *in vivo* condition.
- It appears that multiple mechanisms are responsible for stone fragmentation. Most likely shear waves generated at the outer surface of the stone generate high tensile stresses to induce the first fractures. Then cavitation grinds down the fragments into pieces small enough to pass.
- For tissue injury it appears that once detectable cavitation occurs, the kidney tissue suffers widespread damage. The initiation of detectable cavitation appears to be associated with rupture of smaller order vessels and this may be due to mechanical rupture of the vessel wall by direct stress or by localized invagination induced by a collapsing bubble.
- Firing shock waves more slowly results in better stone comminution and reduced tissue damage.
- Since its inception, lithotripsy has undergone a fascinating evolution. Water-bath-type, EHLs have given way to modular, highly portable lithotripters, many of which employ electromagnetic shock-wave generators. Most lithotripsies are now performed using mobile units delivered by truck to subscribing hospitals. This improved convenience has come at a price, as stone retreatment rates have increased and reports of collateral damage are on the rise. One explanation is that the newer lithotripters are not as efficacious and have the potential to cause more collateral damage.
- New technologies of shock-wave delivery are now being applied to patient treatment. Dual-pulse lithotripsy uses two shock heads to fire separate pulses with the potential for control over the properties of the acoustic field leading to improved efficacy and safety. Likewise, initial success with a new lithotripter that produces a very broad focal zone and is operated at low peak positive pressures suggests that a return to some of the features of the original lithotripter could also be a step toward improved lithotripsy.

CHAPTER 50

Lithotripsy Systems

Geert G. Tailly

Department of Urology and Pediatric Urology, AZ Klina, Brasschaat, Belgium

History of extracorporeal shock-wave lithotripsy

Urolithiasis was documented by the ancient Egyptians, thousands of years BC. It is a common affliction, affecting as many as 15% of humans during their normal lifespan, irrespective of age, gender or ethnicity. Although mortality from stone disease is rare, its morbidity and economic impact are considerable [1, 2].

Prior to the introduction of extracorporeal shock-wave lithotripsy (ESWL) and other minimally invasive techniques, such as percutaneous nephrolithotomy (PCNL) and ureterorenoscopy (URS), open surgery was the principal treatment modality for urolithiasis. The advent of ESWL revolutionized modern stone management.

As early as 1963 physicists at Dornier, an aircraft manufacturer in Friedrichshafen, Germany, investigated the impact of raindrops on flying objects, as these were causing shock waves that not only damaged the outer shell of airplanes but also internal structures. During these experiments, an engineer accidentally discovered the effects of these shock waves on biologic tissue. At the same time, the German Ministry of Defense was showing interest in the interaction between shock waves and biologic tissue. In 1974, a partnership to conduct research on the application of shock waves in humans was formed between Dornier Development and Research (W. Hepp and G. Hoff), the Department of Urology at the Ludwig–Maximilians Universität in Munich (E. Schmiedt and F. Eisenberger), and the Institute of Surgical Research at the same university (W. Brendel and Ch. Chaussy). Funding was obtained through the German Research and Technology Ministry [3–5].

Early on it was found that shock waves caused no damage when travelling through muscle, fat or connective tissue, except at transition zones with high acoustic impedance. It was proposed that shock waves could be used to fragment kidney stones [3, 4]. In the first experiments, a light-gas gun was used to elicit a shock wave in an open waterbath containing a stone. With a focused wave it proved possible to fragment the stone. To obtain optimal propagation of the shock wave through human tissue, water was chosen as the coupling medium: water has acoustic properties nearly identical to those of human tissue. It also proved easy to generate shock waves under water using the discharge of an electrode in a semi-ellipsoid reflector.

The original idea was to fragment a stone with one single shot. Therefore, the energy needed to produce a shock wave that could do and for safety, the effect of such a shockwave on biological structures needed to be determined [6]. Furthermore, the shock-wave circuit needed to produce the underwater spark gap discharge, the electrode or spark gap itself, and focusing using a semi-ellipsoid reflector were investigated. The first shock-wave lithotripter, TM1, was built.

It was realized that imaging was needed to properly position the stone to be fragmented in the second focus of the semi-ellipsoid reflector. A second lithotripter, TM2, with an improved shock-wave generator and an ultrasound A-scanner integrated into the ellipsoid was

Smith's Textbook of Endourology, Third Edition. Edited by Arthur D. Smith, Gopal H. Badlani, Glenn M. Preminger, Louis R. Kavoussi.

built. With the ultrasound technology available at that time, however, it proved virtually impossible to adequately target kidney stones *in vivo*.

In the early animal experiments a form of "carpet bombing" was used to fragment stones *in vivo*. The important conclusions of these experiments were that [3, 4]:

• Stone fragmentation with high-energy shock waves and without direct contact with the shock wave source was possible.
• Trauma to the kidney and the surrounding tissues could be excluded.
• Spontaneous passage of the fragmented stones was possible, provided the fragments were small enough.
• Ultrasound technology at that time did not allow proper targeting *in vivo*.

Although not easily integrated into the experimental lithotripter, fluoroscopy was then chosen to target the stones: two conventional X-ray C-arms were incorporated in the lithotripter.

Further *in vitro* studies of the capacity of shock-wave generators showed that generators with a lower capacity produced complete and fine fragmentation at much lower energy doses than those with higher capacity.

The first lithotripter for human treatments, Human Model 1 or HM1, was built in 1979. Patient selection for the first treatments was very strict:

• A radio-opaque stone not larger than a cherry stone in the renal pelvis;
• Unobstructed urological tract;
• No urinary tract infection;
• No comorbidities.

The first patient was successfully treated on a Dornier HM1 by Christian Chaussy, B. Forssmann, and D. Jocham in 1980 [7]. The results of the first clinical study on 221 treatments in 206 patients were published in 1982 [8].

To propagate the new technique as reproducible and safe, the HM1 needed several improvements:

• Improved X-ray system;
• Improved patient support;
• Improved installation to provide the 1200 L of degassed water for the waterbath;
• Improved shock-wave generator;
• An ellipsoid with a treatment depth of 13 cm.

The Dornier Human Model 3 (Dornier HM3) was born.

In 1983 the second lithotripsy center worldwide was opened in the Department of Urology (F. Eisenberger) of the Katharinen Hospital in Stuttgart, Germany. In 1984 the first Dornier HM3 in the USA was installed in the Methodist Hospital in Indianapolis, IN, USA (Daniel M. Newman and James E. Lingeman). A study for marketing approval by the Food and Drug Administration (FDA) was monitored by Georges Drach [9]. The rest is history . . .

Lithotripters were originally devices dedicated to ESWL. Modern stone management demands a judicious combination of endourologic techniques and ESWL, and there is an evolution towards the construction of multifunctional urologic workstations.

Components of a lithotripter

The Dornier HM3 represented the archetype of the first-generation lithotripter and was characterized by a large water bath in which the patient was immersed for optimal shock-wave coupling. Equipped with an electrohydraulic shock-wave source and an ellipsoidal reflector with a small aperture to focus the shockwave, the treatment required general or spinal anesthesia. With bidirectional fluoroscopic imaging system, the stone could be targeted and be in the therapeutic focus F2. Multifunctional or multidisciplinary use was not possible. The results achieved with this device are still considered the baseline for comparison in evaluating all new devices.

Second-generation lithotripters utilize an electrohydraulic, electromagnetic, or piezoelectric shock-wave source. Transmission of the shock wave is achieved with a water cushion or partial water bath. The stone is localized with an ultrasonic or fluoroscopic imaging system [10–13]. The anesthesia requirements usually are limited to intravenous sedation. Multifunctional or multidisciplinary use is limited.

Third-generation lithotripters are also equipped with an electrohydraulic, electromagnetic, or piezoelectric shock-wave source. All systems allow anesthesia-free treatments. They use fluoroscopy and ultrasound, alternately or simultaneously, to target the stones. Finally, all components are integrated into a multifunctional system with a treatment table, allowing both ESWL and endourologic procedures to be performed with the same device.

Shock-wave sources

Shock waves are acoustic waves, which are mechanical waves consisting of pressure and density variations which can travel through media in any phase, i.e. gas, liquid, or solid. They are also referred to as pressure waves as they propagate through a medium by alternating decompression and compression of the medium. At media interfaces, absorption, reflection or refraction of the shock waves can occur [14]. An acoustic wave of very short duration is called an acoustic pulse and a shock wave is a very short acoustic pulse. Positive pressure rises to maximum in a very short time, followed by a short phase of negative pressure. As the wave propagates through the medium, it becomes ever steeper until it forms a shock wave, which is characterized by a sudden drop from positive to negative pressure. The

short phase of negative pressure generates cavitation in the transmission medium. The bubbles induced by cavitation subsequently collapse violently and create microjets or secondary shock waves. For medical purposes, shock waves are generated in water and transmitted into the patient's body using a (partial) water bath or a water cushion for coupling. Water is chosen as the transmission medium as it has comparable acoustic properties to those of human tissue, leading to impedance matching with low reflection at the contact surface between the water bath or water cushion and the patient.

In the Dornier HM3, the first commercially available lithotripter, shock waves were generated using an electrohydraulic shock-wave source. In second- and third-generation lithotripters any of the three types of shock-wave generation are used: electrohydraulic, electromagnetic, and piezoelectric.

Electrohydraulic shock-wave sources

Electrohydraulic shock-wave generation

Electrohydraulic shock-wave generation is based on an underwater spark discharge. A spark plug with two opposing electrode tips is positioned in the focus F1 of an ellipsoidal reflector. A capacitor of about 100 nF connected to the spark gap is charged to a voltage of 15–30 kV and then abruptly discharged, producing a fast expanding plasma channel between the electrode tips, and resulting in rapid vaporization of the surrounding water, like a microexplosion. This releases a spherical shock wave that is reflected by the wall of the ellipsoidal reflector towards the therapeutic focus, F2, of the reflector. The intensity of the shock wave can be adjusted by changing the discharge voltage. The treatment depth and focusing are defined by the geometric parameters of the ellipsoidal reflector.

This type of shock wave is still used in lithotripters today, and the shock wave source of the HM3 is still considered to be the most effective of this type. Electrohydraulic shock waves have the disadvantage that the lifespan of the electrode tips is limited to several thousand shocks; degradation of the electrode tips causes output variations and instabilities of the focal position.

Electroconductive shock-wave generation

To compensate for the degradation of the electrode tips, EDAP TMS developed a modified electrohydraulic generator, the DIATRON IV, an electroconductive shock-wave generator.

The electroconductive generator is a 100 nF generator connected to an electrode immersed in a highly conductive solution instead of degassed water. Due to the better conduction of electricity, this highly conductive solution allows an extremely accurate spark position. The interelectrode distance is reduced to 0.25 mm and can be adjusted to compensate for electrode wear. This spark gap technology also allows the generation of a focal zone that varies in size with the power output. An automatic pressure regulator permanently adapts the voltage input to consistently deliver the requested pressure and also controls the total energy delivered to the patient.

Electromagnetic shock-wave sources

"Flat coil" electromagnetic shock-wave emitter

The electromagnetic shock-wave emitter (EMSE; Dornier, Siemens) features a flat coil that generates a strong magnetic field when a high current pulse flows through it. This field causes an isolated metallic membrane to be repelled into the surrounding water, the water in the vicinity of the membrane is compressed, and a plane acoustic pulse is released and focused into the therapeutic focal area by a lens. The pressure across the membrane surface is essentially constant. During propagation to the focal area, the pressure pulse undergoes nonlinear effects, leading to the generation of a shock wave. Specifically, the pulse's rising slope becomes steeper and the pulse duration becomes shorter. Since the electromagnetic shock-wave generation principle does not rely on the dielectric breakdown of a liquid, all the associated threshold effects and arc-forming instabilities are avoided. An EMSE can therefore produce effective pressure pulses over a very wide intensity range with a high degree of reproducibility.

The lifespan of the EMSE is of the order of one million pulses. An EMSE does not show progressive degradation in its output power but it needs to be exchanged on a regular basis when the insulating materials and metals have reached their endurance limits.

The plane acoustic pulse generated by the EMSE is focused by an acoustic lens. The choice of the diameter of the EMSE and the focal length of the lens define the aperture angle of the system. The wide dynamic range that is available for EMSE systems, together with the wide choice of aperture angles, provides a unique toolbox for the therapy head designer, serving the different needs of shock-wave field shaping in lithotripsy, in orthopedic shock-wave application, and in other emerging applications. An EMSE is easily incorporated into a multifunctional device. Newer EMSE designs provide treatment results comparable to or even better than the results with the unmodified Dornier HM3.

STORZ electromagnetic shock-wave source: cylinder source with parabolic reflector

The electromagnetic cylinder source was also developed to overcome some of the drawbacks of the powerful but

unstable spark gap technology with a short electrode lifespan. The cylinder generator is based on a hollow electromagnetic cylinder composed of a cylindrical coil covered by an insulating membrane, which again is covered by an electrically conducting membrane of high strength. An intense pulse current with short rise time generates repelling pulse forces due to electromagnetic induction. When immersed in water, the radially expanding membrane generates, primarily, an acoustic cylinder wave which is focused by a special rotational parabolic reflector. This works on the same principle as a loudspeaker, but with very intense and short acoustic pulses.

The cylindrical coil/membrane configuration is very stable and delivers more than one million pulses without degradation or significant fluctuations of acoustic energy. The parabolic reflector can be designed with large apertures and, accordingly, large aperture angles without technical limitations. Due to the large aperture angle, the acoustic energy can be concentrated to laterally narrow and axially short focal zones with high peak pressure and high energy flux density values. Thus, the fragmentation shock-wave energy is restricted to a relatively small area, reducing tissue lesions in front or behind the target stone. Also, anesthesia requirements and shock-wave load affecting the coupling area at skin level are minimized. In contrast to the electrohydraulic spark gap technology, the energy level of each single shock-wave pulse can be precisely adjusted between very low (painless) and powerful settings, exactly matching the pain tolerance of the patient.

The generator configuration featuring a hollow cylinder provides sufficient space for favorable in-line localizations, either for fluoroscopic or ultrasonic targeting.

Piezoelectric shock-wave sources

Piezoelectric shock-wave generation was developed simultaneously by EDAP and Wolf [15–19]. The conversion of electric to acoustic energy takes place in ceramic platelets that expand or contract in the surrounding water because of the piezoelectric effect when a pulse of several thousand volts is applied. Several dozen to several thousand platelets are usually mounted on a spherical segment transmitting the shock wave into the center of the sphere through direct focusing. However, compared to other shock-wave sources, the intensity of a typical piezoelectric generator is lower and a large converter surface is required to mount the platelets. To provide sharp focusing of the acoustic pulse, the diameter of a piezoelectric source needs to be large. Consequently, the large diameter of a piezoelectric dish compromises its easy incorporation into a multifunctional device.

The piezoelectric shock-wave source of the Wolf Piezolith 3000 features a double layer of piezoceramic elements (double layer piezo-technology).

Each type of shock-wave source produces a shock-wave, i.e. an acoustic pulse of which the energy is focused towards and concentrated in the therapeutic focus. In an electrohydraulic lithoptripter the focusing is achieved by a semi-ellipsoid reflector, whereas in an electromagnetic lithotripter shock waves are focused using an acoustic lens or a parabolic reflector. In a piezoelectric system there is no focusing as such. Each ceramic crystal should be considered as a separate point source that produces its own miniature shock wave. The ceramic crystals are arranged on a dish that directs the point sources towards the therapeutic focus, where the accumulation of the energy from all these separate point sources produces sufficient energy for stone fragmentation [direct focusing lithotripsy (DFL)].

Introduction to shock-wave physics

A shock wave is an acoustic pulse characterized by a very fast rise time, a very high overpressure, a very short pulse duration, and a phase of underpressure.

The physics of shock waves is very complex [14], and a basic understanding of some of the parameters in shock-wave physics is useful.

Energy flux density in the focus.

The energy flux density (ED) is a measure of energy concentration:

$$\mathrm{ED} = \frac{\mathrm{Energy}}{\mathrm{Area}}$$

In focused shock-wave systems, the same total energy passes through a decreasing area as the wave travels towards the focal area. Thus the ED increases and reaches its maximum at the focus.

In extensive experiments, Loske found that ED correlates very well with stone fragmentation [20]. He also noted that the negative part of the shockwave (p–), supposedly mainly responsible for the cavitation effect, reaches its maximum below F2. As cavitation is deemed one of the main causes of shock-wave-related tissue damage, it is suggested that treatment outcomes may be improved by positioning the stone several millimeters below F2 (“prefocal alignment”).

Focus size

According to the International Electrotechnical Commission (IEC) standard 61846 (Ultrasonics/Pressure pulse lithotripters/Characteristics of Fields, International Electrotechnical Commission, Geneva, Switzerland), the

focus size in one dimension is the width of the pressure curve where the pressure has decreased to half of the peak pressure. This is also referred to as the −6 dB focus, which is a measure relative to the peak pressure.

Effective energy

The effective energy (E_{12mm}) is a measure of the energy per shock wave that is transmitted through a circular area of 12 mm in diameter, representing a typical stone size of 12 mm. The calculation of the E_{12mm} is based on the integration of the ED over a circular area of 12-mm diameter. The E_{12mm} provides good correlation with the disintegration capacity of a lithotripter. Comparison of different lithotripters remains difficult, however.

Effect of the aperture angle

For the same E_{12mm} delivered into the focus, a shock-wave source with a larger aperture angle will have a smaller −6 dB focus, a sharper focus with higher pressure, and a higher focal ED, whereas a shock-wave source with a smaller aperture angle will be characterized by a larger −6 dB focus, a less sharp focus with lower pressure and a lower focal ED.

Maximum treatment depth

The maximum treatment depth is the distance between the shock-wave head and the point of highest pressure in front of this. This is the geometric focus. The shock-wave focus however is cigar shaped, with the axial dimension longer than the lateral. This means that there is still energy that may be sufficient to break a stone beyond the geometric focus. This is referred to as the "blast path."

In their published specifications, some manufacturers may "extend" their treatment depth by also incorporating the blast path, thus adding half of the focal length to the geometric focus and "stealing" some distance.

Clinical relevance of focus size

There is an ongoing debate about the ideal focus size in a lithotripter [21, 22]. The ideal focus would be a spherical volume exactly matching the size of the targeted stone, thus limiting the administration of energy to the stone and avoiding hitting the surrounding tissue, leading to adverse tissue effects [21, 22]. However, this is technically not feasible. Today's lithotripters have a cigar-shaped focus with energy delivered in front, behind (blast path), and adjacent to the target.

A small focus is highly confined and sharp. The higher pressure in a small focus leads to high efficiency in fragmenting hard stones. In order to obtain optimal fragmentation and to avoid adverse tissue effects, precise targeting is essential.

In a large focus, pressure is lower. Precise targeting is less critical but there is an increased analgesia need and a higher risk of adverse tissue effects. Sometimes there is a demand for larger focal zones in order to treat larger target volumes, even if surrounding tissue may be affected more than technically necessary. To respond to this demand Storz introduced the dual focus technology. The design of the electromagnetic cylinder source offers the possibility to select different focal zones, precise and extended, according to clinical and anatomic conditions. By modification of the electrical excitation of the coil, longer pulses may be generated, which, in turn, stretch the focal zone, both laterally and axially.

The Wolf Piezolith 3000 features a triple focus: F1 = small focus with high ED; F2 = intermediate focus with medium-to-high ED; and F3 = larger focus with medium ED.

Prospective trials to investigate the potential clinical benefits of selectable foci would be useful.

Shock-wave interaction mechanisms

It is generally assumed that a combination of four different mechanisms is involved in the interaction between shock waves and the targeted stone: Hopkinson effect, cavitation, quasistatic squeezing, and dynamic fatigue [10]. It is also assumed, that cavitation and shear forces (Hopkinson effect) are the main culprits in the origin of adverse tissue effects. Although both shear forces and cavitation are also important in the stone comminution process, avoidance of their negative effects is considered important in reducing adverse effects due to shock waves.

The idea behind a dual pulse technique [23, 24] is to "fill" the negative part of the pressure pulse with a positive pressure pulse. In the Direx Duet, dual shock-wave sources are used. Fired synchronized or asynchronized they allow an increase in the total pressure and the shock-wave rate. Sheir *et al*. [23] demonstrated improved stone comminution with a synchronized discharge of a twin pulse. In another study by the same group higher performance and efficacy with this twin-head, twin-pulse technique was demonstrated [24]. At the same time, this technique produced far less parenchymal damage than with the use of a single treatment head. Theoretically, this would reduce cavitation and improve disintegration.

Eisenmenger advocates the use of a wide focus with lower pressure to enhance quasistatic squeezing, as this will presumably reduce tissue trauma and improve disintegration [25–27]. This low pressure–wide focus technology is incorporated in the Lithospace (Advanced Shockwave Technology GmbH, Germany).

Coupling

As already mentioned, shock waves are acoustic waves that travel through a medium by alternating decompression and compression of the medium. Absorption, reflection or refraction of the shock waves can occur at interfaces between media with different acoustic impedance.

As water has comparable acoustic properties to human tissue, shock waves are generated and transmitted in water. In order to minimize energy loss of the shock wave at the interface between the patient and the shock wave source, coupling between shock wave source and patient is extremely important [27].

Total immersion of the patient in a water bath with degassed water where the shock wave is generated (Dornier HM3) is still considered the ideal coupling system. Second- and third-generation lithotripters, however, feature a "dry" coupling, which consists of a water-filled cushion that is inflated and pressed against the patient. The water cushion is made of elastic PVC or silicone, and is capable of adapting to the body contour of the patient. In order to guarantee good acoustic transmission, the water cushion is coupled to the patient through the application of ultrasound gel. In this process, both air bubbles in the coupling gel and folds in the water cushion could impair the transmission of acoustic waves. Even tiny air bubbles in this interface can lead to uncontrolled shock-wave attenuation. In an *in vitro* experiment, Pishchalnikov *et al.* [28] found a 20–40% reduction in fragmentation when air bubbles covered an area equal to 2% of the cushion surface [28]. Decoupling the cushion from the test basin and recoupling it led to a drastic increase in air inclusions. This has led to the recommendation that, if the patient is decoupled during treatment, the coupling procedure must be repeated, including cleansing the coupling cushion and subsequently reapplying gel.

Based on their own stone model, Jain *et al*. were able to identify a considerable influence of air inclusions on the erosion capacity of the shock wave [29]. After experimenting with various techniques for gel application, as a method of choice Neucks *et al.* [30] recommend applying the gel as a bolus, specifically from a vessel with a large opening. A small vessel opening and manual distribution of the gel lead to increased air pockets and poor disintegration results. Bergsdorf *et al*. also recommend the selection of a proper coupling gel disc or gel with low viscosity and the accurate removal of air bubbles to improve efficiency in SWL [31].

Imaging systems

Adequate imaging is vital to the success of ESWL:
- Localization and targeting of the stone;
- Surveillance of treatment progress;
- Identification of fragmentation.

Imaging modalities available on a lithotripter will also to a great extent define treatment strategies.

Early lithotripters were equipped either with ultrasound or fluoroscopy (X-ray). In order to meet all the challenges in modern integrated stone management, current lithotripters should ideally be equipped with both imaging modalities to be used either independently and alternately, or simultaneously. Online use of both modalities is essential.

Fluoroscopy allows targeting of radio-opaque stones at all levels of the urinary tract. Direct targeting of radiolucent stones is impossible, however. Also, smaller renal stones may prove more difficult to locate than with ultrasound. Further drawbacks are the absence of realtime imaging and the exposure to radiation.

With ultrasound it is generally impossible to locate stones in the major part of the ureter, but it allows direct visualization of radiolucent stones and offers easier targeting of smaller renal stones. Its major advantage, however, is realtime imaging, which provides better monitoring of the fragmentation process in the absence of exposure to radiation.

Machines where both ultrasound and X-ray are integrated offer the most versatile imaging and targeting possibilities. Ideally, these machines offer simultaneous online use of both ultrasound and X-ray. Targeting versatility is further improved by the possibility to couple the therapy head to the patient both under and above the treatment table.

Improved imaging and improved targeting will have a positive effect on the effectiveness quotient (EQ).

Lithotripter design

Dedicated or multifunctional machine?

In the first years following its introduction, ESWL was the privilege of high-volume stone centers. This was mainly due to the high costs of the first lithotripters: high capital, running, and maintenance costs. As they were "dedicated" to SWL, these machines were only operated in large centers with a high volume of stone patients.

The construction of less expensive second- and third-generation lithotripters with lower capital, running, and maintenance costs made ESWL available in more and more centers, leading to a reduction in the number of patients treated per stone center.

Stone therapy guidelines from international expert boards consider ESWL to be the first-choice treatment for most types of stones. However, in some indications, endourologic procedures give equivalent or better results as compared to ESWL. In modern stone management, ESWL and endourology are complementary. Lithotripters should ideally support the urologists in any of these modalities. Consequently, in the past two

decades lithotripters have undergone a transition from pure shock-wave generating devices to multifunctional urologic workstations.

One of the key components of such urologic workstations is the patient table. An increasing number of obese patients require high load capacity tables with maximum accessibility in order to be able to approach them from all sides. For fluoroscopic imaging both in ESWL and endourologic procedures, the tabletop needs to be radiotransparent.

Imaging modalities in a multifunctional workstation need to support the wide range of therapeutic options in urology. Large image intensifiers of up to 16 inches ideally offer a large field of view of nearly the entire urinary tract. Full digitization of the X-ray imaging chain provides excellent image quality at low radiation dose. Increasing awareness of radiation safety and dose reduction make ultrasound stone localization an ideal tool for stone targeting and accurate therapy monitoring. Last but not least, a high performance shock-wave source, which ideally can be coupled to the patient in an over- and under-table position, completes the design of a multifunctional lithotripter.

Figure 50.1 Modular design: AST Lithospace (reproduced courtesy of Advanced Shockwave Technology GmbH).

Figure 50.2 Modular design: Wolf Piezolith 3000 (reproduced courtesy of Richard Wolf GmbH).

Integrated or modular?

Multifunctional machines can have a modular design, where all components are separate modules to be "connected" according to need, or an integrated design where all components are integrated in the machine and ideally adapted to their function. A third design, the "hybrid", offers integration of imaging and/or therapy head in a common console with a detached treatment table.

Modular design

In a lithotripter with a modular design (Figures 50.1 and 50.2) the shock-wave source, imaging components, and treatment table are separate modules that need to be connected to perform ESWL or endourologic procedures.

As the imaging components, a fluoroscopic C-arm and an ultrasound machine, usually are available on site, investment cost is limited to the shock-wave module and the treatment table. The imaging components can also be used for other purposes, both in urology and other departments. Modular systems have no need for a dedicated lithotripsy room and are easily transported from one center to another.

Due to the combination *ad hoc* of different modules, the footprint is larger and the floor is cluttered with an array of machinery. In endourologic procedures, this footprint is further enlarged by the addition of an electrosurgical unit, light sources, and monitors, etc. The uro-table is less urologist friendly with limited accessibility, and overall handling is more complicated.

Integrated design

In an integrated design, the different components, shock-wave source, imaging, and treatment table, are fully integrated in one stand-alone system (Figures 50.3–50.5). These systems have a small footprint compared to the modular and hybrid designs. Due to the optimal integration and synchronization of their high end components to form a synergistic system, these machines offer maximal versatility in targeting and positioning for ESWL. Uro-table function usually is excellent and offers great comfort in the performance of endourologic procedures. Ideally this patient table is

Figure 50.3 Integrated design: Dornier Gemini (reproduced courtesy of Dornier MedTech GmbH).

Figure 50.4 Integrated design: Siemens Lithoskop (reproduced courtesy of Siemens AG).

Figure 50.5 Integrated design: Storz Modulith SLX-F2 (reproduced courtesy of Storz Medical AG).

entirely radiotransparent, accessible over 360°, and able to bear obese patients.

The higher investment cost and the fixed installation in a dedicated endourology/ESWL room may prohibit its acquisition by centers with limited patient loads.

Hybrid design

In these machines imaging (fluoroscopy and/or ultrasound) and shock-wave source are mounted on a combined console (Figure 50.6). The patient treatment table is a stand-alone component to be added to the system for ESWL or endourologic procedures. Both investment cost and footprint are between that for a machine with an integrated design and a device with a modular design. These systems are easily transportable and do not need a dedicated room. Some of the components (imaging, patient table) are suited for multifunctional and multidisciplinary usage. Uro-table function usually is adequate and overall ease of handling is between that for the modular and integrated designs.

Performance of lithotripters

To measure the performance of a lithotripter, formulas have been devised that take into account stone-free rate, retreatment rate, and auxiliary procedure rate.

The original effectiveness quotient (EQ_A) was defined by Denstedt *et al.* [10, 32]:

$$EQ_A = \frac{\%\ \text{Stone-free patients}}{100\% + \%\ \text{retreatment} + \%\ \text{auxillary procedures post-ESWL}} \times 100$$

The "extended EQ" or EQ_B [10] and the "modified EQ" or EQ_{mod} [10] were defined in order to fine tune the performance estimations:

$$EQ_B = \frac{\%\ \text{Stone-free patients}}{\begin{array}{l}100\% + \%\ \text{retreatment}\\ +\%\ \text{auxillary procedures}\\ \quad \text{pre- and post-ESWL}\end{array}} \times 100$$

$$EQ_{mod} = \frac{\begin{array}{l}\%\ \text{Stone-free patients} -\\ \%\ \text{curative auxillary procedures}\end{array}}{\begin{array}{l}100\% + \%\ \text{re-ESWL}\\ +\%\ \text{pre-ESWL auxillary procedures}\\ +\%\ \text{post-ESWL auxillary procedures}\end{array}} \times 100$$

Although these formulas represent a mathematic tool to quantify and compare the performance of lithotripters, they only quantify stone-free rate, auxiliary procedure rate, and retreatment rate. A number of other factors are not readily quantifiable, but do play an important role in the final outcome of stone management by SWL: Shock-wave source, stone burden, stone impaction, imaging modality and quality, targeting, analgesia regimen, shock-wave coupling, shock-wave release frequency, treatment strategy, and experience of the operator. Treatment strategies and the experience and skill of the operator have long been underestimated in the performance of ESWL. Operator skill and experience unquestionably are key factors in success.

Although newer electromagnetic machines perform at least as well or even better than the HM3 (Table 50.1), the unmodified Dornier HM3 is still considered the "gold standard" in ESWL. Results with newer lithotripters are, often erroneously, claimed to be poorer than with the original HM3, and many urologists therefore tend to distrust ESWL in a number of indications.

Factors in the poorer results with modern lithotripters without a doubt are:

- Complexity of shock-wave administration is generally underestimated, especially by new users: lack of background and training in ESWL is often the cause of poorer results with modern machines;

Table 50.1 Range of extended EQ (EQ_B) for Dornier HM3, electrohydraulic, electromagnetic and piezoelectric machines.

	Range	References
Dornier HM3 (unmodified)	25–67	33–44
Electrohydraulic machines	25–67	36, 43, 45–61
Electromagnetic machines	31–80	50, 54, 62–72
Piezoelectric machines	30–64	47, 50, 60, 73–79

- HM3 users were extensively trained prior to certification;
- Newer machines are too often misjudged as "plug-and-play," with little attention paid to proper training of new users.

In order to improve results and reduce complication rate, all (new) users of shock-wave machines should be certified on the basis of:

- A theoretical understanding of the basic physics of shock waves;
- An extensive training in imaging, positioning and targeting, coupling, and treatment strategies;
- A comprehensive understanding of shock-wave complications and the ways to avoid them and improve results.

Although lithotripter manufactures are directing extensive research towards improvements in focal geometry and energy to improve stone disintegration and at the same to reduce collateral damage to the surrounding tissue, together with urology teaching institutions they should also invest in proper training of lithotripter users.

The ideal lithotripter and conclusions

An "ideal" lithotripter would have a high performance shock-wave source producing a spherical focus exactly matching the size of the targeted stone, and with the following energy requirements:

- Moderate peak pressure;
- Sufficient disintegration power (ED and E_{12mm}) to disintegrate hard stones and to compensate for shock-wave attenuation (obesity);
- Minimal cavitation effects and hence minimal risk of adverse tissue effects.

Apart from producing a shock wave with the ideal focus, this high-performance shock-wave source would also meet the following requirements: prolonged lifetime without degradation or significant fluctuations of acoustic energy; wide range of energy settings; adequate treatment depth (minimum 150 mm) to accommodate the ever increasing proportion of obese patients, and be easily incorporated in a multifunctional device. These requirements almost automatically exclude conventional electrohydraulic sources: the lifetime of their electrodes is limited and the degradation of the electrode tips leads to output variations and instabilities of focal point and energy.

Coupling of the therapy head containing the shock-wave source is an important issue. The water cushion needs to be made of a material that easily adapts to the body curves and that causes minimal absorption, reflection or refraction of the traveling shockwave. Also, the ability to couple the treatment head to the patient both in an above- and an under-table position

Figure 50.7 Bilateral over- and under-table position of the therapy head (Dornier Gemini) (reproduced courtesy of Dorner MedTech GmbH).

(Figure 50.7) is a very important asset, specifically in the *in situ* treatment of ureteral stones and especially in obese patients.

Accurate targeting is key to success in SWL and depends on excellent image quality, both fluoroscopic and ultrasonic. In endourologic procedures, image quality is equally important. A large image intensifier (up to 16-inch) offers a large view of nearly the entire urinary tract without the need to move the patient table. Orbital isocentric movements of the X-ray C-arm may prove useful both in SWL and endourology. Full digitization of the X-ray imaging chain guarantees excellent image quality at low radiation dose and allows easy and efficient storage of the images in the patient's records (DICOM capability).

Increasing awareness of radiation safety and dose reduction and the excellent image quality of modern ultrasound machines make ultrasound stone localization an ideal tool for stone targeting and realtime monitoring of the entire treatment. An ideal lithotripter thus should be equipped with excellent imaging, both fluoroscopic and ultrasonic, preferably to be used online and simultaneously.

Another key component of a modern multifunctional lithotripter is the patient table. An ever increasing number of obese and even morbidly obese patients demands a high load capacity of the treatment table. To allow good imaging, the table top needs to be radiotransparent. Finally, in endourologic procedures, such as PCNL, nephrostomy tube placement, etc., maximum accessibility (ideally 360°) of the table from all sides is extremely important.

Good imaging and a careful urologist may provide accurate targeting, but respiratory movements continuously swing the targeted stone in and out of the focus. A hit-and-miss system that keeps track of the stone during respiratory movements and only releases a shock wave when the stone is exactly in the focus would improve outcome and reduce collateral damage to the surrounding tissue. It would of course also slow down treatments. According to newer insights, however, slowing down treatments not only improves treatment efficiency [80, 81], but also reduces overall treatment cost [82].

Finally, this sophisticated piece of equipment should only be operated by an interested and experienced urologist, who has a basic understanding of the physics of shock waves [14, 27] and who is closely involved in all treatment modalities (ESWL, PCNL, URS, retrograde intrarenal surgery) of modern stone management.

A department of urology looking for the ideal lithotripter should therefore also invest in good clinical practice and "good lithotripsy" (Figure 50.8). The actual choice of the ideal lithotripter for any given stone center will depend on the specific requirements of a specific setting. Few centers probably have the high patient load for SWL to justify the acquisition of a dedicated lithotripter. A multifunctional workstation for SWL and endourologic procedures is the best choice for centers with an adequate patient load in both treatment modalities. An integrated or hybrid design makes economic sense in very active stone centers. In centers with a modest patient load, a modular system is probably the better choice.

Our own stone center functions 5 days/week with a patient load of approximately 3000 treatments per year (± 600 ESWL and ± 2400 endourologic procedures). We try to solve any acute stone problem within 24 h of admission, preferably on an outpatient basis. The centerpiece of this "integrated endourology concept" is a high-end multifunctional lithotripter with integrated design.

The number of manufacturers and machines currently on the market prohibits any attempt to provide a complete overview of all systems available at present. Also, companies and machines come and go. Therefore, this overview (Tables 50.2–50.7) is limited to those traditional companies who were and are very much involved in the development of and the continued research in SWL. An exception to this rule was made for the AST Lithospace, a lithotripter designed with a philosophy derived from the theories of Eisenmenger [25, 26]: large focus, low focal pressure.

Multifunctional use	Multifunctional table including Trendelenburg	Multifunctional table including Trendelenburg
Special features	Autopositioning	Therapy head on articulated arm for variation of coupling directions
	Dual focus: precise and extended	
	StormTouch: centralized control station for lithotripsy and endourology equipment	Lithotrack: unique tracking system for 3D positioning of therapy head
	StormBase: lithotripsy databank	Local and remote operation with attachable motor drive for Philips C-arms
	Local and remote control operation	
	Optional: dual monitor arm with touchscreen control	Extreme flexibility for ultrasound localization

Table 50.6 Overview of EDAP TMS lithotripters.

	EDAP TMS Sonolith i-Sys	EDAP TMS Sonolith Praktis
Shock-wave generation		
• Type of SW-Source	Electroconductive (ECL)	Electroconductive (ECL)
• Aperture (mm)	291	219
(degrees)	80	80
• Max treatment depth (mm)	130	170
• Power settings	100	21
• Focus		
– Focus size (–6 dB) in mm	3.2 × 2.6 × 22.4	3.1 × 2.2 × 26.8
– Peak pressure (MPa)	129	124
– ED (mJ/mm^2)	1.27	1.16
Coupling	Water cushion	Water cushion
Imaging		
• Fluoroscopy	Integrated	Add-on C-arm
• Ultrasound	Outline (motorized)	Outline (manual)
Overall design	Hybrid	Modular
Anesthesia	Anesthesia free	Anesthesia free
Multifunctional use	Yes	Yes
Special features		
• Automatic pressure regulator	Yes	Yes
• Autopositioning: "Stone Locking System"	Yes	No
• Fully robotized automatic ultrasound positioning system	Yes	No
• Fully robotized and motorized isocentric movements of X-ray C-arm, ultrasound and shock-wave generator	Yes	No
• Dual X-Ray and ultrasound display	Yes	Yes
• Touchscreen interface	Yes	No
• Simultaneous imaging and SW-release	Yes	Yes

Table 50.7 Overview of the WOLF Piezolith 3000.

Shock-wave generation	
• Type of shock-wave source	Piezoelectric: Double Layer Piezo-technology
• Aperture (mm)	270
(degrees)	74
• Max treatment depth (mm)	165
• Power settings	20 intensity settings
• Focus	Triple focus
– Focus size (–6 dB) in mm	3 × 16/5 × 24/8 × 28
– Peak pressure (MPa)	6–126
– ED (mJ/mm^2)	0.03–1.67
Coupling	Water cushion
Imaging	
• Fluoroscopy	Outline X-Ray with LithoArm
• Ultrasound	In-line ultrasound
Overall design	Modular
Anesthesia	Anesthesia and sedation free
Multifunctional use	Add-on uro-table
Special features	Long-lastie: >>5 000 000 shocks
	Triple focus: three focus sizes
	LithoArm for outline X-ray
	Autopositioning not available

CHAPTER 51
Shock-Wave Treatment of Renal Calculi

Hans-Göran Tiselius
Division of Urology, Department of Clinical Science, Intervention and Technology, Karolinska Institutet, and Department of Urology, Karolinska University Hospital, Stockholm, Sweden

Introduction

Several factors can decide the need for active removal of kidney stones. Pain is the most common reason; either frequent episodes of colic or a constant or intermittent dull ache. Occasionally, hematuria is a symptom that precedes the diagnosis and stone removal is often the only way to eliminate the bleeding. Stone material may harbor bacteria, causing constant bacteriuria or intermittent and frequent episodes of urinary tract infection (UTI). Repeated episodes of obstruction, with or without UTI, can lead to reduced renal function. In addition, renal stones also qualify for removal as a prophylactic step when their size makes spontaneous passage unlikely.

In as much as renal stone formation is associated with a high recurrence risk, it is logical to choose a method that is as effective, minimally invasive, and gentle as possible. Today, extracorporeal shock-wave lithotripsy (ESWL), percutaneous nephrolithotomy (PCNL), retrograde intrarenal surgery (RIRS), and laparoscopic surgery are all minimally invasive techniques, but they do have varying degrees of invasiveness and different advantages and disadvantages.

In this chapter, important aspects of ESWL for treating patients with kidney stones will be discussed. It needs to be emphasized that with the introduction of non- and low-invasive methods, the indications for active stone removal have changed, and accordingly many patients are today treated for stones that previously, when open surgery was the only available method, were left for conservative surveillance and follow-up.

ESWL was introduced in 1980 [1] and was adopted worldwide in 1984. It has become the primary and dominant procedure for treating patients with kidney stones. Based on the experience from several millions of treated patients, this method, undoubtedly, has stood the test of time, but all medical procedures have both advantages and disadvantages and ESWL is no exception. Although both a certain fraction of patients may need more than one ESWL treatment session for an adequate disintegration of kidney stones, and residual fragments are encountered in a substantial number of patients, are matters of concern, the advantages are obvious. ESWL is a noninvasive or extremely low-invasive treatment that, in most patients, can be carried out without general or regional anesthesia on an outpatient basis [2]. Experience has shown that 90–95% of all stones can be satisfactorily disintegrated with ESWL [3]. If this goal cannot be achieved, there are essentially two factors that should be incriminated; first, that the function of the lithotripter is suboptimal [4–8] and second, and in many cases probably more importantly, that insufficient attention has been paid by the operator to various details of the treatment procedure.

In this chapter we consider how the results of ESWL of renal stones can be optimized, while simultaneously taking the necessary steps to avoid complications. The various highlighted issues come partly from our own personal experience of more than 20 000 ESWL sessions carried out with various lithotripters during the past 25

Smith's Textbook of Endourology, Third Edition. Edited by Arthur D. Smith, Gopal H. Badlani, Glenn M. Preminger, Louis R. Kavoussi.

years, and partly from the numerous experimental and clinical reports in the literature during the same period of time.

Description of the stone problem

Of those patients with urinary tract calculi who require or fulfil indications for active stone removal, just over 50% present with kidney stones. It has been estimated that, at least in northern Europe and the USA, the annual incidence of stone disease is between 1500 and 2000 per million population [9, 10]. Moreover, at least 30% of these patients are candidates for active stone removal. This means that at least 250–300 patients per million population need to be considered for stone removal from the kidneys.

These stones have different sizes and chemical composition. The intrarenal location of stones recorded in an unselected group of stone formers, who were referred for stone removal in our department, is shown in Figure 51.1. Stone size is most often expressed in terms of the largest stone diameter, but this measure is too approximate and stone surface area (SA) is a better estimate, calculated from the largest diameter (l) and the width (w) of the stone [11, 12] (Figure 51.2).

$$SA = l \cdot w \cdot \pi \cdot 0.25$$

Today, when computed tomography (CT) examinations are more commonly used, an estimate of the stone volume (SV) can be made from the length (l), width (w), and depth (d):

$$SV = l \cdot w \cdot d \cdot \pi \cdot 0.17$$

Such measurements are, however, not commonly reported in the literature.

The dominant chemical stone constituents are shown in Table 51.1. In addition, mixtures of these stone

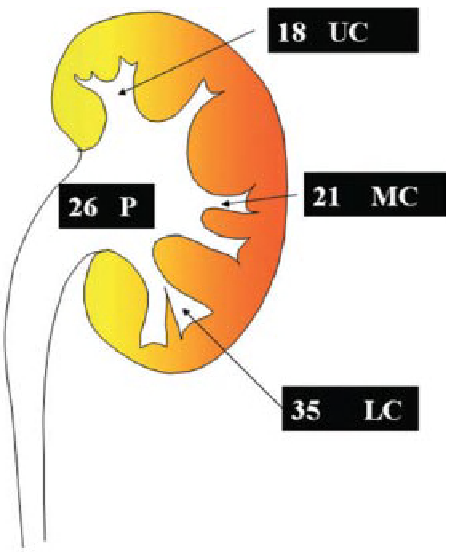

Figure 51.1 Percentage distribution of renal stones in the upper calyx (UC), middle calyx (MC), lower calyx (LC), and renal pelvis (P) recorded in a large unselected group of patients referred for active stone removal.

Table 51.1 Approximate average occurrence of chemical constituents of stones removed from a Swedish population of stone formers.

Main stone constituent	Percentage
Calcium oxalate	60
Calcium oxalate + calcium phosphate	20
Calcium phosphate	5
Infection stone	10
Uric acid	4
Cystine	1

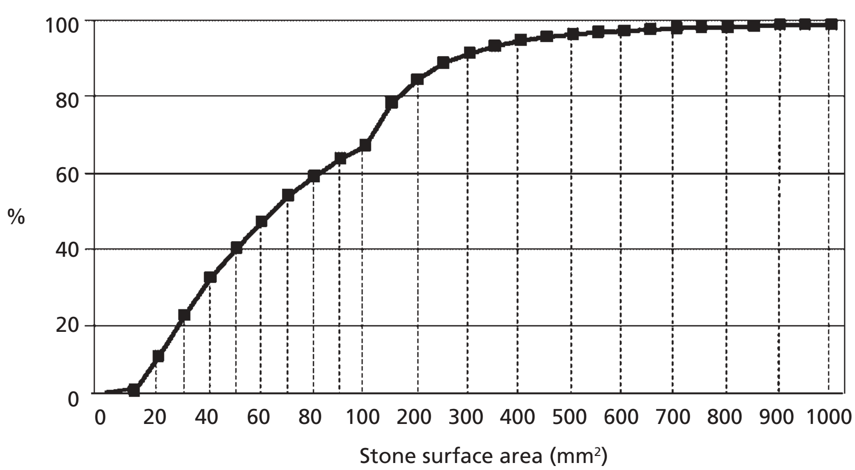

Figure 51.2 Cumulative frequency distribution of stone size expressed in terms of stone surface area. The data were obtained from the same group of patients as in Figure 51.1.

components as well as other unusual crystal phases can be encountered. Although considerable worldwide variations undoubtedly occur in all these variables, the treatment problems and strategic considerations are reasonably similar.

To predict the outcome of ESWL of renal stones and the efforts that may be required to solve particular problems, an understanding of the prerequisites in terms of stone size, stone composition, and stone location is important. Moreover, it is essential to pay due attention to the patient's anatomic and medical condition, as well as to any ongoing pharmacologic treatment.

Disintegration of stones

It is important not to confuse stone disintegration and stone-free rate. Whereas the first variable depends on the lithotripsy efficiency for a particular stone burden, the second is a function of lithotripsy efficacy and fragment elimination properties.

The basic prerequisite for a successful outcome of ESWL is to hit the kidney stone or stones with a sufficient disintegrating energy so that they break into small pieces. Different stones need different levels of energy. Needless to say, a lithotripter must provide sufficient shock-wave power for this purpose. The properties of different lithotripters are discussed in Chapter 50. Production of the Dornier Human Model 3 (HM3) lithotripter stopped in 1986, but it remained the "gold standard" for a considerable period of time, and few later lithotripters have shown similar capacity [5–8]. Why were the results with the original equipment superior for such a long period? A definitive explanation has not been provided, but the original HM3 device differed from modern lithotripters in several aspects and these are important considerations in understanding how optimum results can be obtained with later-generation lithotripters. The shock-wave source was placed in the same water compartment as the patient and there were accordingly minimal energy losses during shock-wave transmission. The shock-wave focus, although with a much lower energy density than in most modern lithotripters, had a very large volume (20 × 90 mm) and the diameter of the shock-wave reflector was accordingly relatively short (15 cm). This means that when the shock wave entered the body it passed through a much smaller tissue volume than in the majority of later-generation lithotripters. The shock waves, moreover, were electrocardiogram (ECG)-triggered and thus were delivered at a frequency close to 1 Hz.

The disintegration of renal stones is successful if fragments are formed that easily can be eliminated through the ureter. Early on it was established that a satisfactory disintegration should result in fragments or gravel of which no single component has a diameter exceeding 4 mm [11]. When remaining fragments have a diameter of 5 mm or more, an optimal disintegration has not been obtained. These definitions have been adhered to in most literature reports and most of the measurements have been made on plain films of kidney, ureter, and bladder (KUB). It needs to be added that more fragments can be identified with CT imaging than on KUB images [13], but for follow-up after ESWL it is much easier to judge stone disintegration with KUB than with CT images [14, 15].

Shock-wave transmission

A fundamental factor in the success of ESWL is uncompromised passage of the shock wave from its source (reflector, therapy head) to the focal point in the patient's body. When it was the practice to immerse the patient in the same water as the shock-wave source, as was the case with the Dornier HM3 device, this was not a potential problem. However, in most modern lithotripters, transmission of the shock wave into the patient's body is accomplished by application of a coupling medium, such as ultrasound jelly or silicon oil. In some lithotripters, the shock wave also has to cross the gap between the therapy head and a plastic foil, before entering the body; silicon oil is used at the first interface and, preferably, degasified water at the second. With all lithotripters, extreme care has to be taken to avoid loss of power during transmission.

Whatever the transmission medium used, it is crucial that a sufficient amount is applied so that the whole shock-wave cone enters the body. Moreover, this medium should be without air bubbles. Air bubbles can adhere to body hairs and for patients with a rich growth of hair, shaving at the point of assumed shock-wave entry should be undertaken to eliminate this cause of shock-wave attenuation.

Depending on the type of lithotripter that is used and whether the patient is treated with the shock wave coming from the back or from the abdominal side, various anatomic structures may interfere with the shock-wave path. If such obstacles are not considered by the operator, they can cause a considerable reduction in or even extinguish the disintegrating power. An imaging system that is in line with the shock-wave path facilitates their identification.

The effect of such interfering structures depends on where the stones and the kidneys are located and of course the direction in which the shock wave is traveling. The shading effect with attenuation of shock-wave energy is greater when the interference caused by an obstructing structure occurs close to the focus than if it occurs at a greater distance from the stone. Figure 51.3 shows a schematic example of how a skeletal structure such as a rib can interfere with the shock wave and

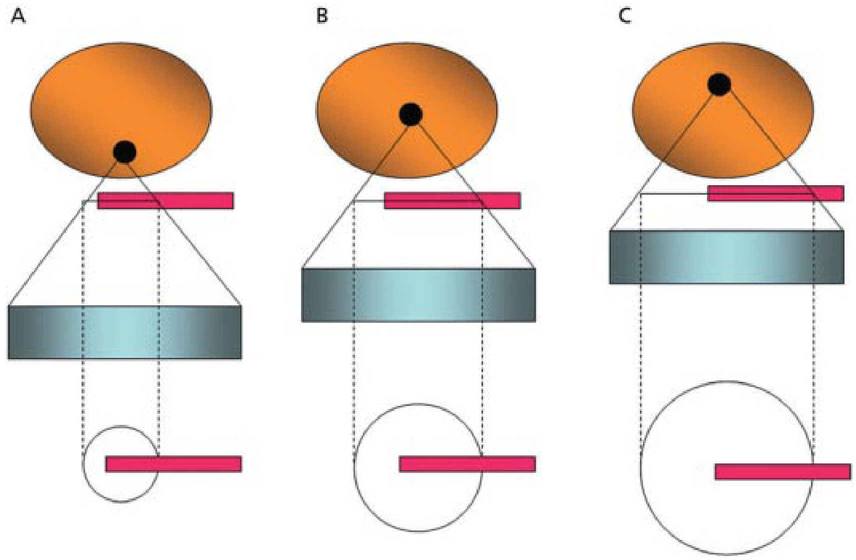

Figure 51.3 Relative interference of a skeletal structure (for instance a rib, indicated by the red rectangle) with the shock wave focused on a stone at various levels in the kidney. (A) Short distance between the stone and the rib and a long distance between the shock-wave source and the rib. The attenuation of the total shock wave energy in that situation is much more pronounced than when relatively smaller parts of the shock wave area are affected (B and C).

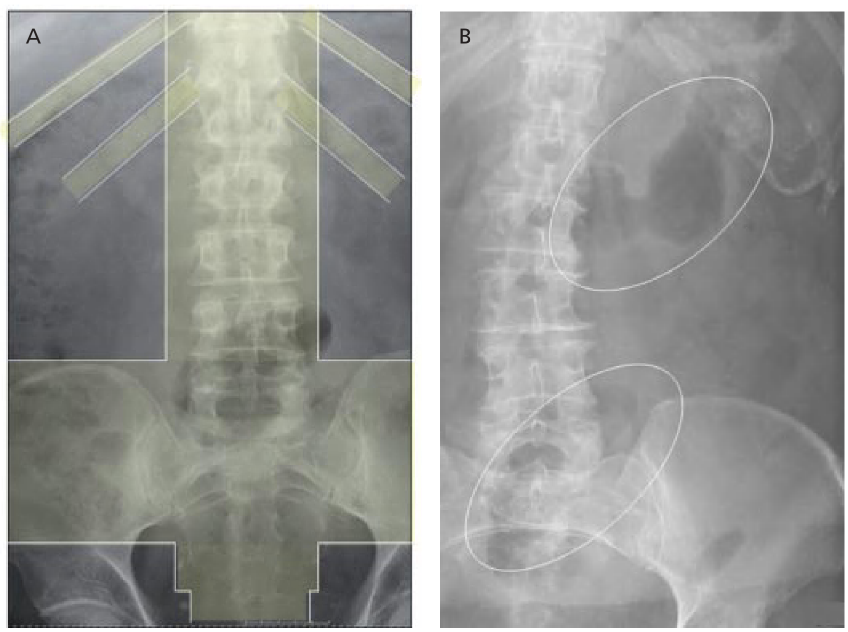

Figure 51.4 (A) Skeletal structures (ribs, spine, pelvic skeleton, and sacrum; highlighted) may attenuate the shock waves when these are directed from the back of the body. The sacrum and lower pelvis are of importance when treating stones in abnormally located kidneys (pelvic and transplanted kidneys). (B) Intestinal gas (ringed) needs attention in patients treated with shock wave directed through the abdominal cavity.

Figure 51.4A shows the important skeletal structures that can interfere with shock-wave propagation. The core of the spine itself or the transverse processes may reduce the transverse area of the shock-wave cone. A similar effect is exerted by the pelvic skeleton in case of kidneys with a low retroperitoneal position or by the ribs for stones located in the kidney. To manage such problems, the patient or the therapy head can be tilted or the shock waves can be administered from the abdominal side.

When the shock wave enters the body through the abdominal cavity, intestinal gas can constitute a barrier to transmission, making shock-wave treatment from that direction impossible or very inefficient (Figure

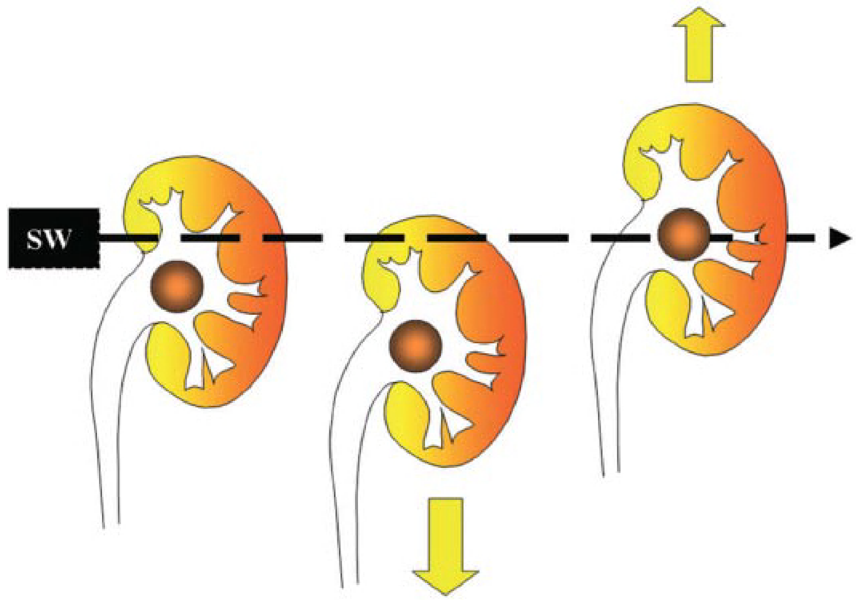

Figure 51.5 Positioning of stone(s) that move with respiration. SW, shock wave.

51.4B). Bowel preparation with dimeticon, enema, or occasionally macrogol (Laxabon) may be helpful, but in some situations it is necessary to postpone the ESWL until there is a more favorable intestinal gas distribution. Although gas can form or redistribute during an ESWL session due to the shock-wave effect on the intestine, a prediction usually can be made from a KUB before the treatment. In cases where it is likely or possible that the shock waves will need to be delivered through the abdominal cavity, we routinely give 300 mg of dimeticon three times daily for 5 days preceding the planned ESWL.

Another obstacle to the shock wave is a thick layer of subcutaneous fat, which has a different acoustic impedance. Moreover, in obese patients there is a longer distance from the skin level to the stone, and this distance has been suggested to be an important predictor for ESWL success [16]. Although the shock-wave attenuation caused by subcutaneous fat and other tissues in most thin and normal-weight patients can be ignored, the much larger tissue volume through which the shock wave has to pass in obese patients may have a significant influence on ESWL efficacy. In obese patients it may be necessary to increase the shock-wave power in order to achieve a satisfactory disintegration of stones [17] and to utilize the blast path technique in order to compensate for an insufficient penetration depth [17, 18].

With a small focal volume and the normal respiratory movement of the kidney, the hit rate of the shock wave can vary considerably. Several methods have been suggested to compensate for that problem. It is important always to place the stone in focus during the expiratory phase, because that is the period during which the kidney and stone remain in the same position for the longest period of time (Figure 51.5). Another trick that can easily be used is to apply a belt across the patient's upper abdomen or lower thoracic cavity in order to reduce the amplitude of the respiratory movements [19], ensuring of course that this does not negatively affect the patient's oxygenation. General anesthesia has been suggested to allow more controlled kidney movement [20, 21] and high-frequency jet ventilation [22], but the need for anesthesia reduces the versatility of ESWL. Another method is respiratory gated shock-wave generation, but that approach has not been particularly successful [23] and is not commonly used.

Experimental studies on the physics of electrohydraulic shock waves in terms of energy density ($\mu J/mm^2$) indicated that better disintegration was obtained when the stone was placed below (in front of) the focal center. Under experimental conditions with an electrohydraulic lithotripter, the maximum disintegration was seen at a distance of 1–2 cm from the expected peak power region [24]. Whether or not this property also is applicable for electromagnetic shock-wave generation is not known, but it may be worthwhile to keep this observation in mind for SWL-resistant renal stones.

Treatment strategy

Optimal disintegration of stones requires a treatment strategy based on an understanding of the physics of the shock waves [25]. In clinical practice, usually a standard schedule with recommendations to the operator on how the treatment should be carried out is followed. Advice is given on the selection of shock-wave generator voltage

(kV, energy level), rate of shock-wave administration, and maximum number of shock waves that should be given. Many of these standardized recommendations are arbitrarily chosen and dependent on the lithotripter used. This static approach is likely to give suboptimal results; moreover, it will undoubtedly often lead to overtreatment both in terms of number of shock waves and energy levels, with associated negative effects on the renal tissue. Recent experimental as well as clinical observations have given a better basis for designing a treatment strategy that hopefully can optimize the outcome and make the treatment even safer.

Shock-wave energy levels

It has been shown that shock-wave energy and stone disintegration improve with increased generator voltage, but significantly so only to a certain level after which the relationship plateaus [24]. A high generator voltage also results in larger fragments than a lower voltage. This property was clearly illustrated by the low power piezoelectronic systems [26]. Thus shock-wave energy should only be increased to a level that results in a satisfactory disintegration. Further increments with the aim of achieving better disintegration or shorter duration of treatment may result in a less satisfactory outcome. On the other hand, it is necessary to use a sufficiently high energy to achieve stone disintegration and that energy is dependent on the chemical composition of the stone. In as much as knowledge of the stone composition is the exception before the treatment, it is highly recommended to start the ESWL at a low energy level and to increase the power slowly until an energy level is reached at which disintegration occurs. Recent clinical observations have demonstrated benefits of increasing the shock-wave energy in a step-wise manner [27–29], but this effect has not been consistently reported [30]. Such a strategy is termed ramping and is commonly applied, at least in most centers that do not use general or regional anesthesia.

The bottom-line of these observations is that shock-wave energy levels should be as low as possible but sufficiently high to achieve stone disintegration. Such an approach also is of fundamental importance for avoiding injury to the renal tissue.

Number of shock waves

It stands to reason that the higher the number of shock waves the greater the risk of renal damage [31]. Certainly, a large number of high-power shock waves should be avoided. A relatively large number of shock waves is, however, necessary for stone disintegration at the energy levels that can be used clinically. Several factors determine the number that is needed, such as the stone volume [32], stone composition [33], size of the patient [16, 32], and the extent to which the shock waves hit the stone. Nevertheless, it can be assumed that many patients are probably over-treated in terms of shock wave number, with the intention to avoid repeat sessions. The problem is that when the surface of a stone disintegrates, fragments will reflect the incoming shock waves. Disintegration of the deeper parts of the stone therefore is difficult to achieve and our experience in such cases is that it is best to plan for a repeat session on another occasion when the small fragments have been eliminated. This is the reason why large renal stones generally require more treatment sessions than small stones. It is important to consider the repeat ESWL session(s) not as failure but as part of a careful and safe treatment strategy.

With a low-power setting it usually is possible to give more shock waves than with a high-power setting. Nevertheless, a maximum of around 2000–3000 shock waves during one treatment session has proven to be practical, possibly with the range of variation depending on the type of lithotripter and location of the stone.

Although these principles should be applied for all patients, it is particularly important to use them when treating children [31] and patients with certain risk factors [17]. General recommendations on energy levels and maximum number of shock waves cannot be given here; they need to be individually established for each lithotripter and each clinical stone situation.

Frequency of shock-wave administration

Today a majority of lithotripters has an electromagnetic shock-wave generator and with this ECG-triggered release of shock waves is unnecessary. Accordingly it is now possible and more common to use a wide range of frequencies for shock-wave administration. Frequencies between 0.5 and 4 Hz (i.e. 30–240/min) have been reported and one apparent advantage is that with a higher frequency the treatment sessions can be shortened.

Several experimental and clinical observations, however, have shown that a low shock-wave rate results in significantly better stone disintegration than a high frequency [27, 34–41]. Most studies have compared 1 Hz and 2 Hz, with best results observed in patients treated with 1 Hz [36–38, 40–42]. In patients given shock waves at 1.0, 1.5, and 2.0 Hz, the conclusion was that the overall outcome was best following treatment with 1.5 Hz [43]. Recent observations have indicated that an even lower frequency of 0.5 Hz may be superior to other frequencies [44, 45]. Such a low frequency setting is, however, not a common feature of most lithotripters today, and unless this approach significantly reduces the total number of shock waves needed, the prolonged duration of the

treatment sessions perhaps makes it less attractive. It is important to note that the benefit of a low shock-wave frequency in terms of stone disintegration was most obvious for stones with a largest diameter exceeding 10 mm [39].

Whether or not a frequency of 1.0 Hz is better than 1.5 Hz is an unresolved issue, but it seems reasonable to avoid frequencies above 1.5 Hz and to reduce the frequency to 1.0 Hz when the expected disintegration is not obtained. In such situations it is reasonable to reduce the shock-wave frequency before further increasing the energy level. In addition to the benefits in terms of stone fragmentation, such a strategy also is recommended for reducing the negative effects of shock waves on the renal tissue [45, 46]. This matter is further discussed below.

The explanation that has been provided for the better disintegration with a lower shock-wave frequency is that cavitation bubbles that have not collapsed when the next shock wave hits, interact with and attenuate the incoming shock wave [47]. Also, cavitation bubbles remaining in the renal tissue are considered important for renal injuries.

Use of increased diuresis

With the intention of creating an expansion chamber around the stone [48] and possibly of moving fragments away from the stone surface, a forced diuresis has been our preference when treating kidney stones. Patients have been given a single 20 mg dose of furosemide together with a high pressure infusion of approximately 1000 mL of Ringer acetate solution during the treatment session. There are no randomized studies proving the efficacy of such a regimen, but experimental as well as clinical data have shown that fluid surrounding the stones may be associated with improved disintegration [48].

Interval between treatment sessions

One clinically highly important and common question concerns the frequency with which ESWL is carried out for kidney stones. Unfortunately this issue has not been fully elucidated. With the HM3 lithotripter, patients sometimes were given a second session after approximately 2 days. With the higher energy flux density of modern lithotripters, it seems wise to wait until the contusion or traumatic injuries to the renal tissue from a previous session have resolved. Kidney tissue damage caused by ischemic changes and reflected in coagulation and fibinolytic factors disappear after about 1 week [49]. Translation of these findings into clinical practice suggests an interval between ESWL sessions of at least 7 days, particularly if the same area of the renal parenchyma will be exposed to a new series of shock waves. In such cases we have routinely allowed 10–14 days between ESWL sessions.

Reduction of renal tissue damage and bleeding

Technical aspects

As mentioned above, a low rather than a high frequency of shock-wave administration, in addition to a better stone disintegration, is associated with less trauma to the kidney. Moreover, the risk of bleeding can be reduced by inducing a vasoconstriction by starting with a number of shock waves at a low power setting [50]. Based on animal experiments, it also has been suggested that the best vasoconstriction is obtained when a pause is introduced after a small initial number of low-power shock waves [27].

Attention to anticoagulation treatment

Although minor hematoma and contusions following ESWL of kidney stones are considered common [51], large and clinically more significant subcapsular bleedings fortunately are rare. When they occur they are, however, usually associated with severe pain, considerable blood loss, and variable effects on renal function. The development of a subcapsular or retroperitoneal hematoma is one of the most severe and feared complications of ESWL and precautions are necessary to counteract this risk. A definitive explanation for all renal hematomas cannot be provided, but certain obvious risk situations must be avoided.

It is essential to document any anticoagulation therapy that the patient is on. Pharmacologic agents containing salicylates should be stopped in due time before the treatment in order to re-establish a normal thrombocytic function. The recommendation is to stop such treatment 7–10 days before ESWL for kidney stones [11]. It needs to be emphasized that certain health and herb preparations contain substances that increase the risk of bleeding; a serious renal hematoma was described in a patient who had taken large amounts of garlic [52]. In all these patients it is good practice to measure the bleeding time and to postpone the treatment when this is prolonged.

Treatment with warfarin and other coumarol derivatives must also be stopped. In these cases it is sometimes necessary to discuss the medication with the patient's internist because problems may arise if it is interfered with. Replacement with small amounts of low molecular heparin (Fragmin) is necessary as long as the INR value is below the therapeutic range. The recommended daily dose of heparin is 2500–5000 U. Exceeding that dose may result in a significantly increased risk of bleed-

ing during or after ESWL. The standard practice in our department is to give the last warfarin dose on the fourth day before the planned treatment, to refrain from warfarin administration during the following 3 days, and to administer low-molecular-weight heparin after the treatment on the day of ESWL. Treatment with a low dose of low-molecular-weight heparin subsequently should continue until a therapeutic INR level is achieved.

Appropriate medical steps need to be taken in all patients with other coagulation or bleeding disorders in order to avoid renal bleeding complications [17, 53].

Increased risk of renal hematoma in patients with hypertension

Numerous reports have shown that hypertension dramatically increases the risk of renal hematoma [17, 51]. ESWL must not be given to patients with hypertension and measurement of the blood pressure before ESWL for kidney stones is mandatory. As there is a relationship between stone formation and hypertension [54], it is not surprising that many patients who come to ESWL have a previously unrecognized hypertension. All these patients should be referred to an internist for adequate treatment before ESWL.

Other conditions associated with increased risk of bleeding

Whenever there is suspicion of calcified or brittle arteries in the kidney, great care should be taken with shock-wave delivery in terms of shock-wave number and power setting. Patients who should be considered at high risk are those aged over 65–70 years, or with diabetes mellitus or a history of hypertension, even when appropriately treated. Based on clinical experience but without specific literature support, it is our practice also to consider patients who have been on any kind of anticoagulation treatment to be at risk.

Management and prevention of complications

Hematoma

Fortunately renal hematoma are rarely encountered, with frequencies in the literature of around 0.5–4% [51, 55]. The diagnosis of a subcapsular or retroperioneal bleed is established with a CT examination. The hemoglobin value should be measured and blood given in accordance with the estimated blood loss. Conservative treatment is almost always the method of choice. Circulatory unstable patients may need intensive care and occasionally intervention or radiologic plugging, but our experience indicates this need is exceptional. Most patients recover well after a few days of bed rest. Renal function should be followed and the hematoma followed with regular CT images.

Infection

Another severe complication is urosepsis. Needless to say, in all patients with UTI or bacteriuria, pre-ESWL treatment with antibiotics according to the sensitivity pattern should be given. Because urinary tract stones frequently are associated with or occur together with asymptomatic bacteriuria, attention has to be paid to the potential risk of developing septicemia when the ESWL is carried out and bacteria are released.

Screening for bacteriuria with a dipstick test is recommended for all patients who come to ESWL. In case of a positive test, as well as in patients with a history of UTI or with a percutaneous nephrostomy catheter, an intravenous dose of antibiotics should be given approximately 1 h before the treatment. Sometimes a previous urine culture can be used to choose the most appropriate antibiotic regimen. In the absence of such information, a broad-spectrum antibiotic should be given intravenously. We have routinely used with great success aminoglycosides, such as gentamicin 120 mg or netilmicin 150 mg, but 1–2 g of ceftazidime or another cephalosporin may be a useful alternative. For a patient in whom the risk of infection is particularly pronounced and no percutaneous nephrostomy catheter is present, it is advisable to insert an internal stent before ESWL. Such a step aims to alleviate the risk of obstruction and stagnation of infected urine. For all patients with a positive bacteria test, a urine culture should be carried out and oral antibiotics continued for an appropriate period of time after the ESWL session.

Steinstrasse

It was an early observation that ESWL of large stones was associated with a risk of developing an obstructing accumulation of stone fragments in the ureter. The condition was called steinstrasse [11]. Only situations similar to that in shown in Figure 51.6 are of clinical relevance and need to be treated appropriately. It is, however, essential to prevent the formation of a steinstrasse. The rule that has been established is to insert a stent when the largest stone diameter exceeds 20 mm or when the stone surface area is greater than 200–300 mm^2 (as measured on a frontal view image) [11]. In some cases with smaller stones it also may be of value to counteract obstruction by stenting, particularly when a rapid passage of fragments can be anticipated and there is a risk of stagnation of infected urine.

Several methods have been suggested for dealing with a steinstrasse if it occurs. In the presence of

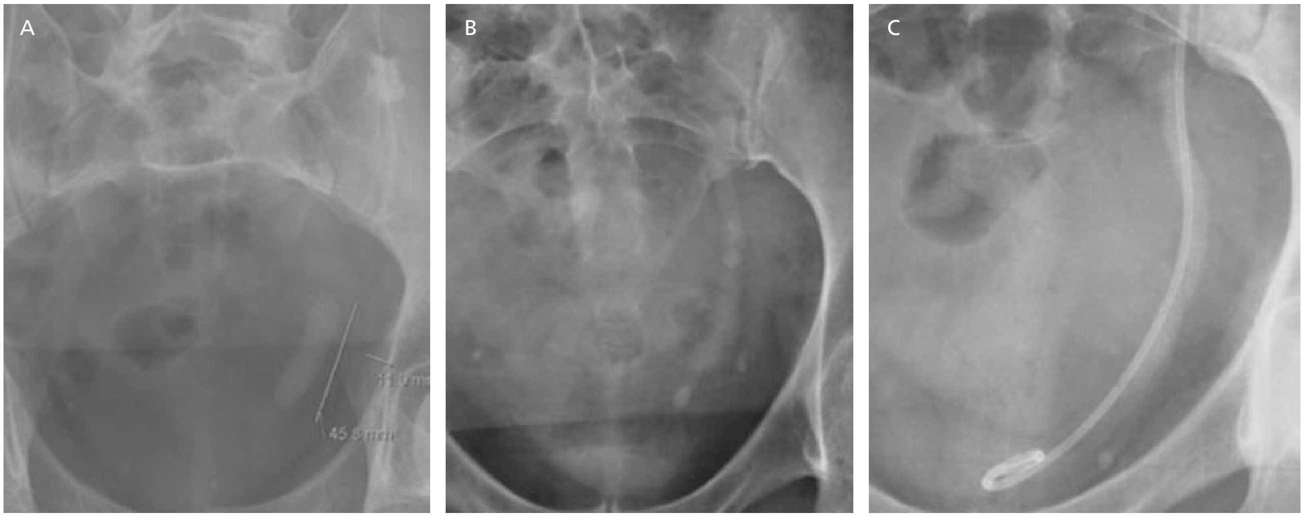

Figure 51.6 (A) Accumulation of well-disintegrated fragments obstructing the urine flow (steinstrasse) following shock-wave lithotripsy of a 30 × 30 mm stone in the renal pelvis. (B) A similar accumulation of fragments, but with larger stone residuals. (C) Accumulation of well-disintegrated fragments along an internal stent.

infection symptoms, the most appropriate step is to insert a percutaneous nephrostomy catheter after which well-disintegrated fragments usually pass. In the absence of infection, ESWL directed towards the steinstrasse may break up the fragment accumulation and disintegrate any leading or imbedded larger fragments (Figure 51.6B). Occasionally, it may be of value to loosen the impaction by instillation of a lubricant jelly through a ureteral catheter and to place a stent afterwards if the steinstrasse can be passed with a guidewire. With these steps almost all fragment accumulations can pass and it is our experience that a ureteroscopic approach is almost never necessary in these patients.

Pain

Episodes of renal colic are a reason for emergency visits or readmittance in the days immediately following ESWL. To counteract such problems, the routine administration of diclofenac twice daily for 5–7 days is recommended [56]. In addition, alpha-receptor antagonists or calcium channel blockers may be useful to facilitate fragment passage [3, 57].

Pharmacologic tissue protection

It has been shown that ESWL generates free radicals and that administration of antioxidants has a tissue protective effect. Treatment with allopuriol may counteract renal injuries [58, 59]. Tissue protection has also been observed with calcium antagonists [60]. Such treatment options should be considered in patients with reduced renal function and in those in whom repeated sessions can be foreseen.

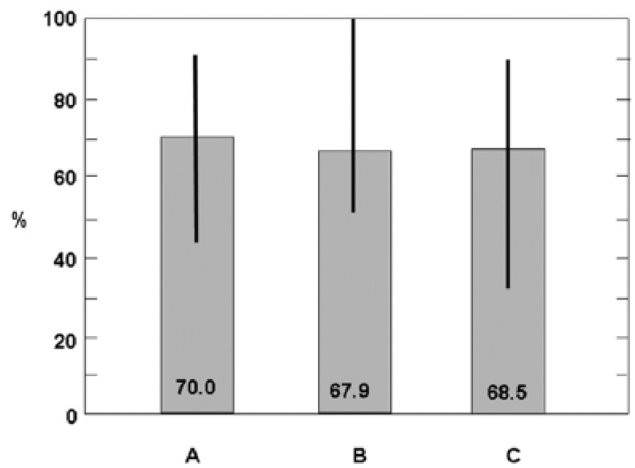

Figure 51.7 Mean and range stone-free rates in patients treated with electrohydraulic lithotripters up to 1989 [61] (A) with second- and third-generation lithotripters up to 1993 [61] (B), and from lithotripsy results reported between 2000 and 2009 [19, 20, 26, 30, 32, 62–69] (C).

Treatment outcome

Results of SWL for kidney stones are summarized in Figure 51.7. Data from the literature up to 1993 showed stone-free rates between 44% and 90% in 3231 patients treated with electrohydraulic lithotripters [61]. With electromagnetically generated shock waves in 16 307 patients, the stone-free rate ranged between 52% and 100%, with a mean stone-free rate of 67.9% [61]. With the piezoelectric technique applied in approximately 2000 patients, between 51% and 75% became stone free. For patients with renal stones treated with modern lithotripters between 2000 and 2009 [19, 20, 26, 30, 32,

62–69], the average stone-free rate was 68.5% (range 31–90%) (Figure 51.7), which is very similar to the rates seen with electromagnetic devices up to 1993. A correct interpretation of these results is, however, seriously hampered by the lack of information on patient selection and referral to ESWL, and the acceptance of repeated session. Nevertheless, the retreatment rate for the electrohydraulic systems varied between 6% and 46%, and for the electromagnetic systems between 7% and 32%. It is of note, and not surprising, that the retreatment rates were highest with the piezoelectric system, ranging between 14% and 51% and averaging 27%.

Of an unselected group of 420 patients with renal stones primarily treated in our department during 2008 with ESWL, excluding those with staghorn stones composed of cystine, calcium oxalate monohydrate, and brushite, 57% were completely stone free and 17% had minor isolated fragments measuring 1 mm or less. Thus, 74% could be regarded as essentially stone free. Another 20% had fragments of 4 mm or less and 4% larger fragments or stones. These results were obtained after 624 sessions, which gives an average of 1.49 sessions per patient. Auxiliary procedures were used in 22% of the patients. The stones had a mean (SD) surface area of 94 (172) mm^2.

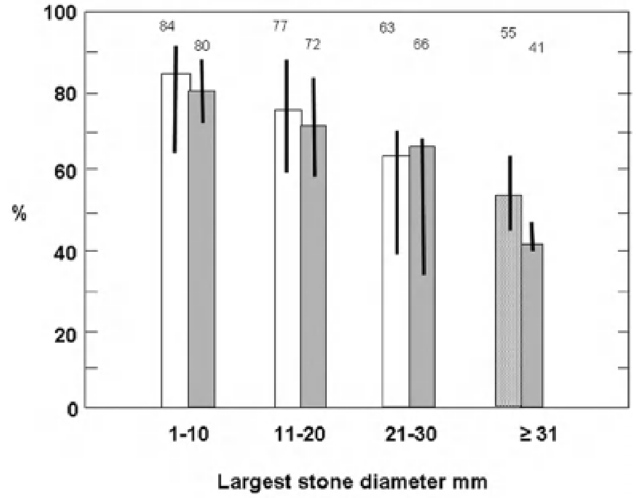

Figure 51.8 Mean and range stone-free rates recorded after shock-wave lithotripsy of stones in different size categories. The data were obtained from reports on treatment with the Dornier HM3 lithotripter (unshaded; the dotted column represents staghorn stones) [61] and with modern lithotripters between 2000 and 2009 (shaded) [3, 32, 63, 64, 70].

Determinants of treatment outcome

Treatment results, need for retreatment and auxiliary procedures, as well as profile of complications are dependent on the type of lithotripter used, its physical properties and disintegration capacity. Moreover, the size and type of stone play a major role.

Stone burden

With a generous and unrestricted attitude to repeat ESWL, it can be stated that approximately 95% of stones can be satisfactorily disintegrated [2, 3]. Large stones, however, require more treatment sessions than small stones and the stone-free rate decreases with increasing stone size (Figure 51.8) [3, 32, 61, 63, 64, 70]. Why large stones, albeit satisfactorily disintegrated, are associated with significantly more residual fragments is less easy to understand. Such an outcome possibly can be explained by disturbed contraction forces of the calyceal system caused by large stones residing in the kidney for a long period of time [71].

In view of the greater need for retreatments and the poor fragment clearance following treatment of large stones, it has been recommended that stones above a certain size are better referred to other low-invasive treatment alternatives, such as PCNL or RIRS, particularly if located in the lower calyces [72]. There is, however, no consensus on the cut-off size. Some authors reserve ESWL for stones with a largest diameter not exceeding 20 mm [2, 19, 73, 74], whereas others set an upper limit of 15 mm [75, 76], 25 mm [77], 30 mm or more [68, 78, 79].

It is necessary also to consider the hardness (fragility) of the stone. Different stone constituents respond very differently to shock waves and clinical observations of their resistance to ESWL have allowed their hardness to be described in terms of their practical hardness factor (HF) [33]: cystine 2.4, brushite 2.2, calcium oxalate monohydrate 1.3, carbonate apatite 1.3, hydroxyapatite 1.1, magnesium ammonium phosphate 1.0, calcium oxalate dihydrate 1.0, and uric acid 1.0. Similar results have been reported by other authors [5, 17, 80, 81]. Knowledge of the stone composition allows a hardness index (HI) to be calculated from the HF [33]. A numerical estimate of the clinically relevant stone burden subsequently can be derived from the surface area and HI [82].

For determination of stone hardness in the absence of information on the chemical composition of the stone, CT examinations can be used as a guide and the stone density expressed in Hounsfield units (HU) [83–85]. There is, however, a considerable overlap between the HU values for different stone components. Recent advances in dual-source CT have proved to be a superior method for identifying various stone constituents, but this methodology is not yet commonly available [86, 87]. Therefore, in the majority of cases, the morphology and hardness of the stones has to be roughly estimated from their appearance on the KUB [14, 15].

Pareek *et al.* found that the best ESWL results were obtained when the stones had a density of less than 900 HU and when the skin–stone distance did not exceed 10 cm [16]. Similar results have subsequently been reported by others [5, 65, 88, 89].

Collecting system anatomy

Anatomic abnormalities may prevent fragment elimination from the kidney in different ways and the effect has to be judged in each individual case. Many of these patients may best be treated with alternative methods, as discussed elsewhere in this book.

Stones in the calyx diverticula are seen relatively often. Although the connection between such cavities and the other parts of the renal collecting system in most cases does not allow passage of fragments, a majority of these patients become asymptomatic after appropriate disintegration [90–92]. Therefore, primary ESWL rather than endoscopy may be a reasonable approach.

In medullary sponge kidneys (tubular ectasia), the stone burden is located inside the dilated collecting tubules and is inaccessible to ESWL. ESWL in those patients, however, may prolong symptom-free intervals by allowing elimination of stone material protruding into the calyces [93].

Stones in children

Several studies have clearly demonstrated that ESWL is an excellent procedure for active stone removal in children [77, 94, 95]. The principles are similar to those for adults with the exception that stents seldom are necessary even when large stones are treated [77]. It is particularly important to use low energy levels and a limited number of shock waves in children. Moreover, for most children it is necessary to use general anesthesia for an optimal treatment.

Stone location and fragment elimination

As illustrated in Figure 51.9, the location of the stone is a determinant of the treatment outcome. Stone-free rate is lowest for stones originally located in the lower calyx, but the differences in mean stone-free rates are relatively small. The lower calyx is the most common place for renal stones when first diagnosed with as many as 35% in that location (see Figure 51.1).

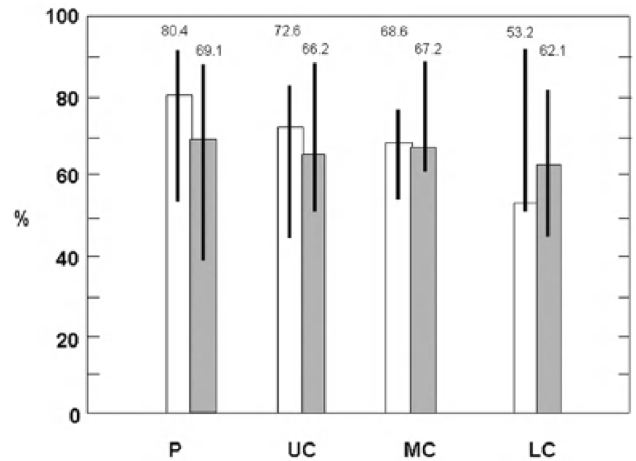

Figure 51.9 Mean and range stone-free rates reported for renal stones located in the renal pelvis (P), upper calyx (UC), middle calyx (MC), and lower calyx (LC) after treatment with the Dornier HM3 lithotripter up to 1993 (unshaded) [61] and with modern lithotripters 2000–2009 (shaded) [3, 32, 62–67, 70, 89]

The occurrence of residual fragments at follow-up is one of the major concerns after ESWL for renal stones. It is well recognized that the majority of residual fragments are found in the lower calyceal system (Figure 51.10A). This is thought to be an effect of gravity, because even for stones initially located and treated in other parts of the kidney, the lower calyces are the most common place for residual fragments. This is shown by the findings in more than 335 patients with residual fragments recorded after ESWL (Figure 51.10B). Although as many as 79% of the residuals were found in the lower calyces, in 34% of the patients the treated stone had not been located in the lower calyx.

Whereas some authors have suggested that stones in the lower calyx, particularly if larger than 10 mm in diameter, should be referred for alternative stone removal methods [96], others have shown that acceptable results can be obtained with ESWL for stones with a largest diameter of up to 20 mm [74].

A large number of reports have dealt with the geometric features of the lower calyceal system and several determinants have been suggested to predict stone clearance [97–102]. Although contradictory results have been reported, outcome of ESWL has been attributed to the calyx length, calyx width, angles of the outflow direction, infundibulum height, as well as the volume of the collecting system [79]. It has thus been suggested that a geometric analysis should be undertaken before deciding on the most appropriate form of treatment [100]. Although these different measurements can be used as a guide to future clearance problems, they usually cannot reliably predict the passage of fragments [103]. Statistical differences in stone-free rates related to anatomic findings are usually small. Most of these geometric analyses have been carried out on urographic images. On standard noncontrast CT examinations without three-dimensional image reconstruction, the corresponding measurements are not easily obtained. It is our opinion that information on the lower calyx anatomy today mainly is of theoreti-

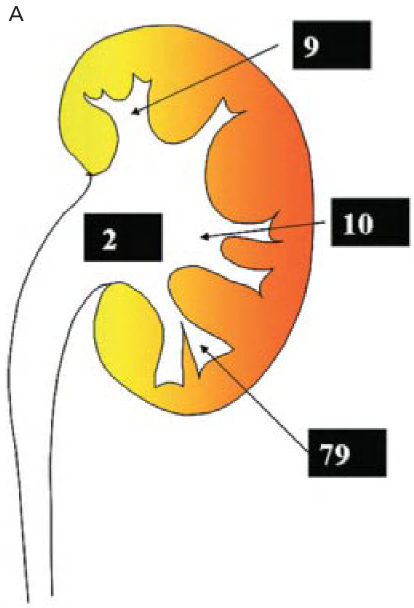

Figure 51.10 (A) Distribution of fragments in 335 patients with residuals after shock-wave lithotripsy and (B) the original location of the treated stones.

cal interest in a close follow-up analysis, and we do not look at the lower calyx anatomy before proceeding to ESWL.

There may, however, be a place for the analysis of lower calyx anatomy with the purpose of selecting those patients who may benefit from procedures aimed at facilitation of fragment elimination [62, 102]. In this regard, some authors have successfully used inversion therapy to improve stone clearance, in combination with vibration or percussion [104, 105]. Even when such an approach cannot be provided, instructing selected patients in various inversion movements may be rewarding.

Pharmacologic treatment aiming at improving stone clearance comprises alpha-adrenergic receptor antagonists, alkaline citrate, and diuretics. In a recent meta-analysis of 29 reports, it was suggested that patients treated for kidney stones should be offered supportive treatment with alpha-receptor blocking agents [57, 106, 107]. Several reports also have shown that treatment with alkaline citrate resulted in a significantly higher stone-free rate than when no such treatment was given [10, 108, 109].

Whether high diuresis after ESWL is of value for faster fragment elimination has not been unequivocally shown, but it is likely that such a regimen may be helpful, at least during the first days following a successful stone disintegration [63].

A major issue of concern is what should be done with those patients in whom residual fragments persist. There is a consensus that those who have *symptomatic* residuals should be offered active stone clearance [11, 53]. ESWL is one option, but alternative methods such as PCNL, RIRS, or chemolysis (when appropriate) should be considered. Similarly, additional treatment should be considered for *asymptomatic* patients with residuals that are unlikely to pass spontaneously through the ureter [11].

For *asymptomatic* smaller residual fragments, in the literature termed clinically insignificant residual fragments (CIRF), there is a lack of consensus on how to proceed, because it is generally assumed that residual fragments constitute a potential risk for new stone formation. Although that is an indisputable argument, far from all fragments will result in the formation of new symptomatic stones. For infection stone residuals, as well as for patients with cystine, uric acid, or brushite residuals, there is a pronounced risk of new stone formation (see below), but for most calcium stone residuals the further course of the disease cannot be predicted and there is no consensus on how to deal with such residuals [110–113]. In a 4-year follow-up of patients with calcium stone residuals (≤4 mm) in our department, 52% had unchanged or insignificantly increased stone volumes. New stone formation unrelated to the residual fragments was seen in 12% and obvious growth or consolidation without any symptoms in 14%, but progress to a symptomatic stone situation requiring repeated stone treatment was seen in only 12% [110]. In other reports the course of residual calcium stone fragments and the need for repeated treatment were at a similar level [110, 113, 114].

It stands to reason that the recurrence rate is higher in kidneys with residual fragments than in those without, but even stone-free patients have been reported to have a higher than expected recurrence rate following SWL (a 5-year risk of approximately 50%) [115]. A definitive explanation for this has not been provided, but it can be assumed that microscopic residual fragments serve as nuclei for new stone formation [116]. It would seem desirable, at least in our opinion, not to aggressively over treat the asymptomatic patients with the aim of making them absolutely free from stone fragments. For patients with residual renal fragments or stones it is, however, essential that a regular follow-up system is part of the long-term management [110, 114]. Moreover, it is recommended that these patients are offered recurrence prevention according to a biochemical risk analysis [10, 67, 110]. It is worthwhile noting that patients with residuals receiving medical treatment after PCNL had a significantly lower risk of developing stone recurrences [117, 118]. How the metabolic evaluation should be carried out is beyond the scope of this chapter [11].

Methods to describe treatment results

A stone-free status is the definite goal of each ESWL, but to achieve this may require several treatment sessions as well as auxiliary procedures. Therefore, ESWL results are often expressed as an efficiency quotient (EQ) according to the following formula:

$$EQ = \frac{100 \cdot SF\%}{100 + repeated\% + auxillary\%}$$

where SF% is the percentage of stone-free patients, and repeated% and auxillary% are the percentage of repeated SWL and auxiliary procedures [119]:

As the result is highly dependent on the stone burden, a stone treatment index (STI) was derived based on the number of stone-free patients (N_{SF}), ESWL sessions ($N_{SESSION}$), auxiliary procedures (N_{AUX}), and complications (N_{COMP}), as well as number of patients treated with regional or general anesthesia (N_{ANE}) [82]. Moreover, the stone burden was expressed as $\text{mean}\left(\sqrt{SA} \cdot HI\right)$, in which SA is the stone surface area and HI an expression of the stone hardness derived from the hardness factors, HF (see above) and the stone composition. To that were added factors for the patients age divided by 50 (Age_R), body mass index (BMI) divided by 25 (BMI_R), and the mean number of anatomic abnormalities (N_{ANA}):

$$STI = \frac{N_{SF} \cdot \left(\sqrt{SA} \cdot HI \cdot BMI_R \cdot Age_R \cdot [1 + N_{ANA}]\right)}{(N_{SESSIONS} + N_{AUX} + N_{ANE} + N_{COMP})}$$

The STI is useful not only for ESWL -treated patients but also for comparison of different stone-removal procedures in both patient groups and individual patients. It should be noted that a high STI is better than a low one. This index can be derived for both stone-free kidneys (STI_{SF}) and for those with a satisfactory disintegration (STI_{FR}). As an example, a 40-year-old patient with a BMI of 30, SA of 100 mm^2 and HI of 1.20, without anatomic abnormalities and who is stone-free after two ESWL sessions without anesthesia, auxiliary procedures, and complications, has an individual STI of 5.76. This can be compared with a similar outcome following URS with one session, one removal of a stent and general anesthesia, which gives an STI of 3.84. Renal stones may require significantly different treatment efforts, as shown in the three examples of ESWL for renal stones in Figures 51.11–51.13. Individual STI values were calculated for each of the four kidneys. For the right kidney with residual fragment in Figure 51.13, the STI reflects the efforts necessary to achieve satisfactory disintegration.

Chemolytic considerations

Whereas calcium stone residual fragments or stones, with the exception of brushite, have a variable course and in many cases appear to remain surprisingly stable, this is not true for infection, cystine, and uric acid stones. These latter stone fragments, as well as brushite residuals, almost always give rise to new stones [110, 114, 120]. In those patients a much more extensive clearance of fragments is necessary and chemolysis is a very useful tool for this.

The primary procedure for removal of partial or complete staghorn infection, cystine, uric acid, and brushite stones is PCNL or occasionally RIRS, but even with these invasive procedures residual stones and fragments will be encountered [117, 121]. A combined so-called "sandwich" approach is often used in such cases [122]. This means that following the primary percutaneous approach, remaining stones are disintegrated with ESWL and in case of persisting residuals a second PCNL or RIRS procedure is used to finally clear the collecting system. When a percutaneous nephrostomy catheter is already in place chemolytic options are available for stones containing magnesium ammonium phosphate, carbonate apatite, brushite, uric acid, and cystine, but not for calcium oxalate stones or stones with a significant fraction of calcium oxalate [123–125]

Hemiacidrin (Renacidin®) [124, 125] or Suby's solution [123] are excellent alternatives for dissolution of infection stone and brushite stone fragments, and are also useful for other calcium phosphate salts. For uric acid stone residuals, alkaline solutions of 0.3 mol/L or 0.6 mol/L THAM (trihydroxy-methyl-amino-methane) can very rapidly clear the system [11, 113]. We routinely use oral chemolysis with alkaline agents in case of uric

Figure 51.11 A 688 mm^2 stone in the right kidney of a 40-year-old woman. The stone situation before treatment (A) comprised three stones with diameters 30 × 24, 11 × 7, and 10 × 8 mm. The kidney became stone-free (E) after three shock-wave lithotripsy sessions with a total of 8450 shock waves (B–D). Treatment was carried out with an internal stent and the STI_{SF} was 4.8.

acid residuals of limited size. The combined use of THAM solutions and acetylcysteine can advantageously be used for elimination of cystine fragments [126, 127]. Chemolytic irrigation may be of value also in those cases where the collecting system is regarded as sufficiently cleared of microscopic residuals.

When chemolytic treatment is carried out it is essential to avoid high pressure infusion. Therefore *two* nephrostomy catheters should be in inserted: one for inflow and one for outflow. Although methods have been designed for pressure measurements, this is usually not a necessary device and we have not used this method in several hundreds of chemolytic treatments. A broad-spectrum antibiotic should be given parenterally before starting chemolysis in order to avoid infection. An internal stent is recommended to maintain a urine flow to the bladder and to avoid stone passage down the ureter.

For patients with soluble staghorn stones who are either medically unfit for general or regional anesthesia or who have other factors excluding percutaneous surgery, a combined approach with repeated ESWL sessions and percutaneous chemolysis can be used (Figure 51.14) [128]. This method has been successful in a number of patients with infection, brushite, uric acid, and cystine stones. The ESWL is used to increase the stone surface area to be exposed to the chemolytic solutions. Although this method is time consuming, it nevertheless provides a treatment alternative for many

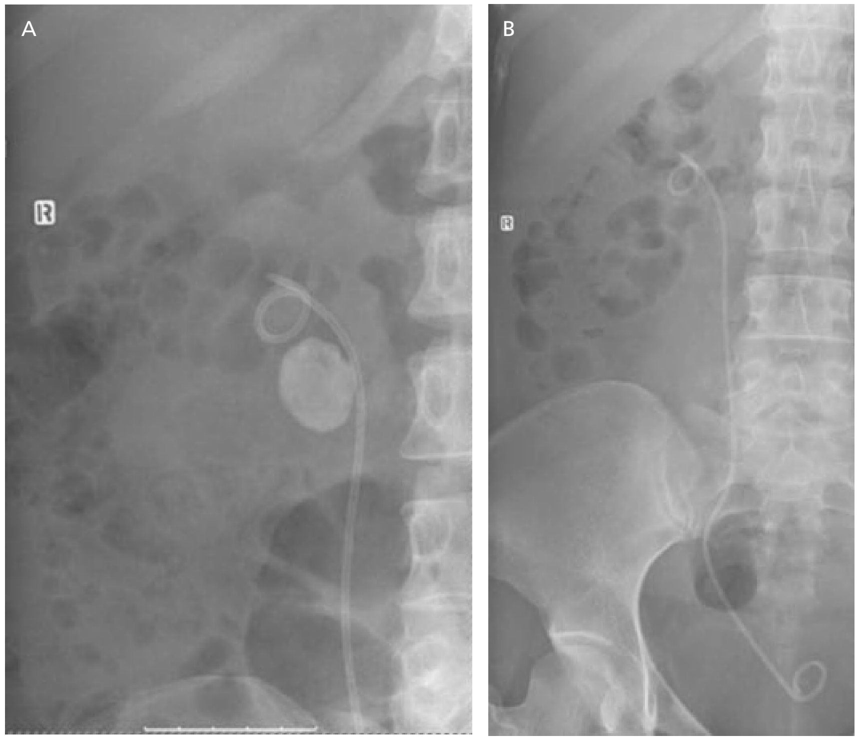

Figure 51.12 (A) Patient with a stone of surface area 358 mm^2 (24 × 19 mm). (B) The stone was sufficiently disintegrated with one shock-wave lithotripsy session (3200 shock waves) and the kidney became stone free. STI_{SF} was 6.4.

patients when other methods are impossible or less desirable.

Chemolytic solutions for different stone components are summarized in Table 51.2.

Recommendations and contraindications

Whether SWL is an appropriate treatment method for a defined stone problem is dictated by several factors. To give strict recommendations is not possible because the attitudes of the patient as well as of the treating urologist, together with both medical and economic issues, play a role. One fundamental prerequisite is that there is an outflow from the kidney that will permit fragments to pass.

The question of which patients should be referred to ESWL can be addressed by first identifying those patients in whom ESWL is not an indication. Pregnancy is an absolute contraindication to ESWL [17]. Similarly, uncorrected bleeding disorders, ongoing medication with anticoagulation agents, as well as untreated hypertension exclude patients from ESWL. It is considered contraindicated to give shock waves to patients with aortic or renal artery aneurysms, at least for stones that are located close to such pathologic structures [73]. This is probably a wise recommendation, but ESWL in patients with aortic aneurysms is not an absolute contraindication [129].

For patients with complete or partial staghorn stones, ESWL is not the first choice. Although large infection stones can be appropriately eliminated by a combined approach with ESWL and chemolysis (see above), ESWL monotherapy is discouraged. Stones of other chemical composition should be removed by PCNL, particularly when composed of cystine, calcium oxalate monohydrate, or brushite.

The upper size limit for a stone that should be treated with ESWL has been a matter of debate. Most authors agree that ESWL is the primary method for stones with a diameter up to 20 mm [113], but others have treated larger stones. There is, however, a need to consider that treating larger stones will require several treatment sessions as well as stenting, but that is a choice that the patient often makes given the noninvasive or at least minimally invasive character of ESWL.

Specific factors that should be taken into account are the stone composition and location. Large brushite, calcium oxalate monohydrate, and cystine stones are usually more effectively eliminated percutaneously. This may also be the case for large stones in the lower calyx, as discussed above.

Recommendations for successful ESWL for renal stones are listed in Table 51.3 and suggestions for post-ESWL treatment to avoid pain and improve fragment elimination in Table 51.4.

Figure 51.13 Bilateral stones in a 75-year-old woman of surface areas (A) 637 mm^2 and (B) 196 mm^2. There were three shock-wave lithotripsy sessions for the right-sided stone (7300 shock waves) and one for the stone on the left side (700 shock waves). Whereas the left kidney became stone free (C, D), the right kidney had a collection of asymptomatic fragments at follow-up (E–G). Stents were used bilaterally to allow for safe treatment of the two kidneys at short intervals. STI_{SF} for the left stone was 8.7. The corresponding STI_{FR} for the right stone (*disintegrated* stone) was 7.8 (although expressed in terms of stone-free kidney, the right STI is of course 0).

Figure 51.14 (A, B) A complete infection staghorn stone with a surface area of 1770 mm^2 successfully treated with a combination of shock-wave lithotripsy (SWL) and chemolysis. Treatment was completed in 10 days with three SWL sessions (5100 shock waves) and 15 000 mL of hemiacidrin. The short interval between the repeat sessions was possible because different parts of the kidney were treated on each occasion.

Table 51.2 Which chemolytic agent should be chosen?

Stone constituent	Chemolytic agent
Magnesium ammonium phosphate (struvite)	Hemiacidrin (Renacidin) 10% (or 5%) *or* Suby's solution G
Carbonate apatite	Hemiacidrin (Renacidin) 10% (or 5%) *or* Suby's solution G
Brushite (calcium hydrogen phosphate)	Hemiacidrin (Renacidin) 10% (or 5%) *or* Suby's solution G
Hydroxyapatite	Hemiacidrin (Renacidin) 10% (or 5%) or Suby's solution G
Octacalcium phosphate	Hemiacidrin (Renacidin) 10% (or 5%) *or* Suby's solution G
Calcium oxalate	No chemolytic agent available
Uric acid*	THAM solution 0.6 or 0.3 mol/L
Ammonium urate	No chemolytic agent available
Xanthine	No chemolytic agent available
Cystine	THAM solution 0.6 or 0.3 mol/L in combination with acetylcysteine solution 2–5% (pH ~8)
2,8-dihydroxyadeneine	No chemolytic agent available

*Also add oral chemolysis with alkali (sodium bicarbonate, potassium citrate, or sodium potassium citrate) and allopurinol to reduce high levels of P-urate and U-urate.

Table 51.3 Recommendations for successful shock-wave lithotripsy for renal stones.

Make sure that the coupling between the shock-wave source and the patient is optimal
Place the stone in focus during the expiratory phase
Reduce respiratory movement with a belt
Check the position of the stone frequently during treatment
Start the treatment at a low energy level
After a small series of shock waves, a pause of 2–3 min may be of value, particularly in patients with a high risk of bleeding complications
Never exceed a shock-wave frequency above 90 per minute or 1.5 Hz
Reduce the frequency to 60 per minute or 1.0 Hz if insufficient or absent disintegration
Do not exceed shock-wave energy above levels where an obvious disintegration occurs
Avoid unnecessary over-treatment
In case of "jumping stones," reduce the shockwave energy
In patients for whom repeated sessions are expected, consider administration of renal tissue protective agents
For patients with a positive bacteriuria test, positive culture or a history of urinary tract infection, give an intravenous dose of a broad-spectrum antibiotic 1 h before the treatment
Never treat patients with uncorrected hypertension
Never treat patients with uncorrected coagulation disorders
Stop treatment with salicylates and warfarin as detailed in the text
Give sufficient analgesics and sedatives to avoid patient movements and to allow an uncompromised choice of shock-wave energy
Make sure that the shock-wave path is free
A forced diuresis during the treatment may be beneficial
Allow 10–14 days to elapse between repeated treatment sessions
If no disintegration can be observed, search for possible obstacles
If extraventricular beats occur, consider use of ECG-triggered shock waves. In bradycardia, give atropine
Administer oxygen during the treatment and measure oxygen saturation continuously

Table 51.4 Suggestions for post-shock-wave lithotripsy treatment to avoid pain and improve fragment elimination.

Give 50 mg diclofenac suppositories twice daily for 5–7 days
For appropriate patients, give an alpha-receptor blocker for 10–30 days
A treatment course of a diuretic may be useful, and potassium citrate may compensate for potassium losses
For appropriate patients, give instructions for inversion treatment

CHAPTER 52
Shock-Wave Lithotripsy of Ureteral Calculi

Damien M. Bolton & Anthony Ta
Department of Urology, University of Melbourne; Department of Surgery, Austin Hospital, Melbourne, Victoria, Australia

Introduction

The last decade has seen the mainstream use of flexible and small-caliber ureteroscopy (URS) combined with laser techniques for stone fragmentation, in addition to traditional pneumatic devices. In spite of this progression towards improved efficacy and availability of URS for treatment of ureteric calculi, extracorporeal shock-wave lithotripsy (ESWL) remains a valid first-line treatment for ureteric stone disease due to its noninvasive nature, safety, and ease of treatment.

Shock-wave lithotripsy principles

Evolution of technology and physics

The ability of lithotripters to fragment stones relies on laws of acoustic physics, namely the production of a wave of energy consisting of a sharp peak in positive pressure followed by a trailing negative wave. All lithotripsy machines require a method of stone localization, an energy source to generate a shock wave, a device to focus the shock wave on an intended target, and a coupling mechanism to transfer the shock wave to the body [1–3]. The three main types of shock-wave generation available for use are electrohydraulic, piezoelectric, and electromagnetic [4].

Ultrasound and fluoroscopy remain the standard for ureteral stone localization prior to ESWL, and combined systems allow some compensation for the potential limitations of each modality. Ultrasound is useful for localization and realtime monitoring of stone manipulation for renal calculi and radiolucent stones, but is inferior to fluoroscopy for ureteral stone localization due to a lack of a clear acoustic interface. The presence of a hydronephrotic ureter will assist localization of ureteral stones to be treated by ESWL. Distal to areas of ureteric dilation, the use of ultrasound as a localization technique for ESWL is limited. Conversely, fluoroscopy requires additional operating room space and stone radio-opacity, and carries inherent risks of ionizing radiation. Radiolucent ureteral stones can be located with fluoroscopy using contrast, which can be instilled in an intravenous, retrograde or antegrade fashion [5]. Modular designs of current modern lithotripters allow use of fluoroscopy without the unit being attached to the machine, thus minimizing space requirements and allowing portability [6].

Mechanisms of stone fragmentation

Continued research in the last decade has improved our understanding of the mechanism of stone destruction, as well as concomitant tissue injury in ESWL. Urinary calculi are vulnerable to shock waves due to the imperfections in their structure, resulting from heterogenous crystallization of minerals and organic matrix. The mechanisms for stone fragmentation are a combination of compressive fracture, spallation, and cavitation [4].

Smith's Textbook of Endourology, Third Edition. Edited by Arthur D. Smith, Gopal H. Badlani, Glenn M. Preminger, Louis R. Kavoussi.

Compressive fracture

As the shock wave is propelled through tissue and to the stone, tensile cracking results due to forces imparting stress on stone imperfections and defects. Eisenmenger used *in vitro* studies of stone fragmentation to propose a circumferential "squeezing" effect of shock waves on urinary stones, based on the premise that shock waves travel faster in stone than water [7]. Provided that the focal point of the shock waves generated is larger than the stone, this should result in perpendicular and parallel cracks.

Spallation

This process involves the reflection and inversion of part of the shock wave back on to the stone as the shock wave leaves the posterior surface of the stone. This is due to the change in impedance at the stone–fluid interface, and if the reflected negative pressure exceeds the tensile strength of the stone, comminution of the stone will occur at sites of weakness.

Cavitation

This process involves the formation and collapse of bubbles as sound waves propagate through a fluid medium. As the generated shock wave travels through the body, the negative pressure wave creates bubbles at the stone–fluid interface, which increase in size as pressure falls. As the pressure increases with the positive component of the wave, these bubbles collapse violently and the resultant energy release contributes significantly to stone fragmentation [8–11].

Dynamic fatigue

During the course of ESWL treatment, the stone is subjected to multiple forces, leading to cracks and changes to its surface. The accumulation of damage leads to "dynamic fatigue," and ultimately, fragmentation of the stone [12].

Mechanisms of tissue injury

Although clinical experience with ESWL has demonstrated its safety, undesired tissue injury remains a concern, and studies in the last decade have shed significant light on the mechanisms of ESWL-induced tissue injury. In a review of current literature, Weizer *et al*. categorized these mechanisms: cavitation-induced renal injury, renal vasoconstriction and ESWL-induced renal injury, and free radical-induced renal injury [4].

As mentioned above, cavitation bubbles contribute significantly to stone fragmentation. However, tissue injury resulting from their formation in microvasculature and renal tissues is an unwanted effect of ESWL [13, 14]. Further studies are required to demonstrate if modifications to lithotripters to reduce parenchymal and intravascular cavitation can be performed without compromising stone destruction. These potential collateral tissue effects of cavitation are fortunately less critical in the management of ureteral as opposed to renal calculi (see Chapter 51), as surrounding tissue is less important to homeostatic function than renal parenchyma.

Factors influencing extracorporeal shock-wave lithotripsy in the management of ureteral calculi

Stone factors

Stone location

Proximal ureteric calculi

Calculi located in the proximal ureter are generally easily treated with ESWL (Figure 52.1). Some studies have shown earlier clearance of such stones using URS techniques as compared to ESWL, with the latter potentially requiring multiple attempts before radiologic evidence of stone clearance. This may mean a longer symptomatic period, as well as further use of hospital resources to retreat these patients. A prospective trial performed by Karlsen *et al*. in 2007 demonstrated a 58% stone-free rate with ESWL for 5–10-mm proximal ureteric stones at 3 weeks, compared to 79% with URS, although the difference was not statistically significant [15]. However, at 3 months similar stone-free rates were seen (88% for ESWL and 89% for URS). In 2008, Ziaee *et al*. performed a prospective trial comparing ESWL to URS for 10–15-mm proximal ureteric stones and demonstrated overall stone-free rates at 3 months of 78.6% and 72.5%, respectively [16]. Both ESWL and URS are considered appropriate first-line choices for treatment of proximal ureteric stones with overall stone-free rates of 82% and 81%, respectively, as shown in a recent large meta-analysis [17].

Mid-ureteric calculi

Calculi located in the mid-ureter are generally more difficult to treat with ESWL. This can be attributable to the increased difficulty of stone localization and inefficiency of shock-wave transference to the stone. Treatment using a posteriorly-oriented therapy head is often improbable due to the attrition of wave energy on the bony pelvis, and as such ESWL may be best performed in the prone position. In a large series of 598 patients, Tiselius was able to demonstrate stone-free rates of 97.8% for mid-ureteric calculi with one or more sessions

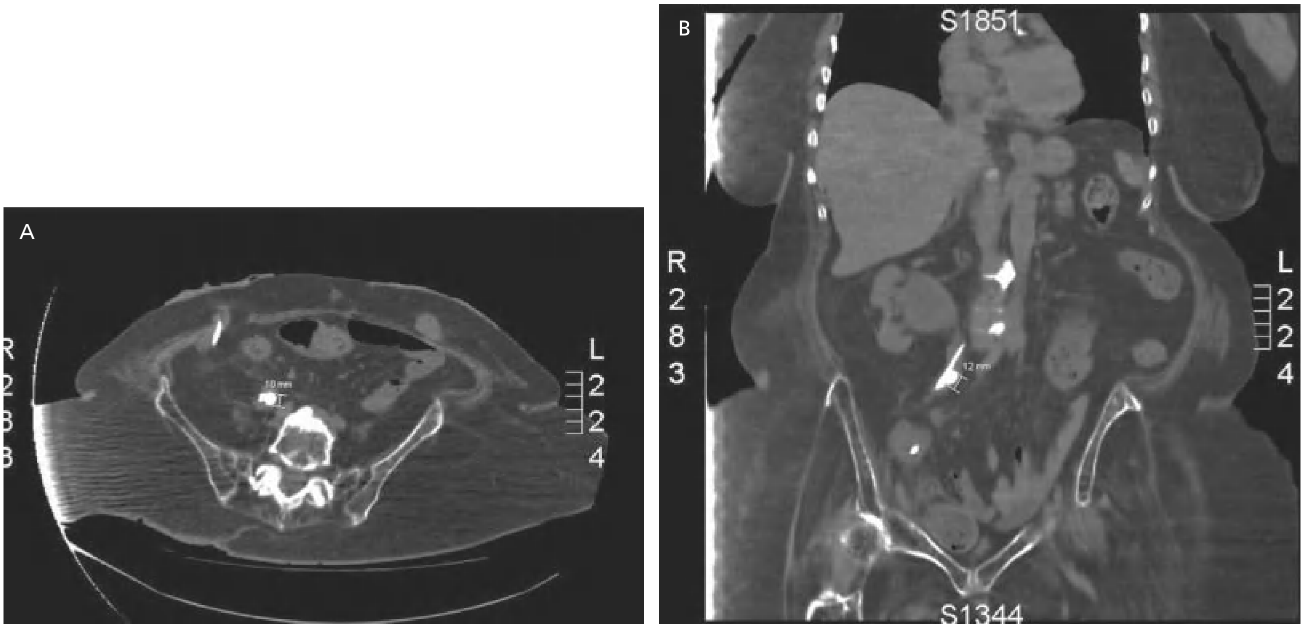

Figure 52.1 (A) Axial and (B) coronal CT images of a 72-year-old female with T5 paraplegia and ileal conduit and colostomy. Images demonstrate a 12-mm stone at the superior end of the right mid ureter adjacent to a ureteric stent.

of ESWL, but with a single treatment session being successful in 66.7%, compared to 73.1% and 83.2% in the proximal and distal ureter, respectively [18]. Stone-free rates for mid-ureteric stones by means of URS as a single procedure have been shown to be as high as 80–90% [19, 20]. For mid-ureteric calculi larger than 15 mm, stone clearance at 3 months was shown to be only 39.1% for ESWL, compared to 79.2% for URS [20].

Distal ureteric calculi

Stones located in the distal ureter are also amenable to treatment with SWL. The American Urological Association (AUA) Clinical Guideline Panel in both 1997 and 2007, the latter in conjunction with the European Association of Urology (EAU), performed a meta-analysis that demonstrated median stone-free rates of 86% and 74% for distal ureteric stones less and greater than 10 mm, respectively [17]. For URS, median stone-free rates of 97% and 93% were demonstrated for stones less and greater than 10 mm, respectively.

Stone size

Several studies have demonstrated that increasing stone size is associated with lower clearance rates with ESWL than for comparable smaller stones, necessitating retreatment with ESWL or secondary procedures [16, 21–23]. When comparing ESWL to URS for larger stones (>10 mm) in the proximal and distal ureter, stone-free rates are higher in the URS managed groups [17]. Stone-free rates for proximal ureteric calculi have been reported to fall from 80% to 44% for calculi larger than 10 mm [24].

However, with multiple ESWL sessions, some authors have shown overall stone-free rates for proximal and distal stones to reach 96.1% and 97.9%, respectively [18]. The AUA/EUA meta-analysis failed to show any statistically significant difference between ESWL and URS for successful treatment of ureteric stones of all sizes [17]. Other studies have shown ESWL to be inferior to URS for treatment of larger stones in the mid ureter, with multiple sessions often required, and thus most authors advocate URS as the treatment of choice for calculi in this location [20, 25]. However, the use of URS requires regional or general anesthesia, and is associated with greater morbidity and cost, especially if endoscopic laser techniques are used.

Stone composition

Stone composition plays a very important role in determining the success of ESWL. Failures are more likely to occur in treating uric acid and cystine calculi. Although these stones form a minority of ureteral calculi, with the large remainder of patients having calcium-based stones, their identification may preclude treatment with ESWL.

Uric acid stones in the ureter may be difficult to localize with fluoroscopy and ultrasound, despite being easily fragmented with ESWL. Computed tomography (CT) imaging can be used with some confidence to

predict the presence of uric acid stones by measurement of Hounsfield units (HU). In general, pure uric acid stones have a lower CT density (<1000 HU) and calcium stones a higher CT density (>1000 HU) [26–28]. Higher stone attenuation on CT (e.g. >750 HU) has also been shown to be associated with poorer fragmentation rates, independent of other factors such as stone size and location [29–32].

Cystine stones are relatively radiolucent and are often refractory to treatment with ESWL, although the degree of resistance is variable [17]. Patients with cystinuria are often identified based on their propensity to develop recurrent stones, which typically occur earlier in life. Some authors have suggested cystine stones are more likely to be refractory to ESWL treatment as they have a smoother contour on plain imaging and higher CT density [33, 34].

Technical factors

Choice of lithotripter

Whilst the principles of ESWL remain unchanged, the evolution of lithotripters in the last three decades has seen the development of smaller machines with less focal point pressure, in order to reduce anesthetic and analgesic requirements. Consequently, second- and third-generation machines have been shown to have inferior stone fragmentation rates compared to the original first-generation lithotripter, the Dornier HM3. The advent of third-generation machines, however, introduced computer monitoring of treatment in addition to dual-modality stone localizing systems. Further advances have also seen increased machine portability.

To the present day, the Dornier HM3 remains the benchmark and reference for ESWL treatment of renal and ureteric calculi. Comparisons to second- and third-generation machines have yielded mixed results, with several studies demonstrating superior stone-free rates with the Dornier HM3 compared to published results for later generation machines [35–37]. Stone-free rates after a single treatment have been reported to be as high as 90% or more [38, 39]. Gerber *et al*. performed a randomized trial comparing three generations of lithotripters, including the Dornier HM3, and demonstrated inferior stone-free rates with the two newer generation machines [40]. Conversely, Tiselius was able to achieve overall stone-free rates of 97% with third-generation lithotripters, with modest retreatment rates [18].

Few studies currently exist comparing the latest fourth-generation machines with the Dornier HM3 for treatment of ureteral calculi. Nomikos *et al*. compared over 300 patients treated for renal calculi with a fourth-generation lithotripter (Sonolith Vision) to a similar population previously treated with the Dornier HM3, and demonstrated comparable results but with lower analgesic requirements [41]. In a similarly designed study, Pemberton *et al*. compared 107 patients with ureteric calculi treated with the Sonolith Vision lithotripter to a similar group treated with a third-generation machine (Dornier Compact Delta). The authors demonstrated superior stone-free and retreatment rates with the fourth-generation machine, with efficacy approaching that of the Dornier HM3 [42].

Delivery of shock waves: rate and voltage stepping

Some urologists tend to deliver more shock waves in a short period of time as a means to improve treatment and anesthesia times for stone fragmentation. In a recent review, however, Weizer *et al*. showed that a shock rate of 60/min resulted in superior stone-free rates compared to 120 shocks/min in calculi of less than 2 cm [4]. A more recent meta-analysis by Semins *et al*. also demonstrated that 60 shocks/min are superior to 120 shocks/min in achieving successful ESWL [43].

Stone fragmentation relies on a combination of two fundamental mechanisms: stress waves, which are dominant in the initial disintegration of stones, and cavitation bubbles, which produce fine fragments and are critical for success of ESWL. However, the formation and collapse of cavitation bubbles may result in unwanted collateral tissue injury; thus, the optimal use of both can improve stone communition and reduce tissue damage [44]. Voltage stepping, which involves initiating treatment at a low kilovoltage (kV) and then gradually increasing power output, has also been suggested as a means to improve stone fragmentation (compared to constant output voltage) based on *in vitro* studies [45]. Using porcine kidneys, Connors *et al.* demonstrated that voltage stepping results in less shock-wave-induced renal injury [46]. However, the authors acknowledged that this effect may have been due to a period of "rest" applied between the ramps of voltage (approximately 3–4 min). Voltage stepping may also allow for improved patient comfort and reduced pain.

In 2010, Lambert *et al*. demonstrated evidence for both improved stone communition and reduced renal injury in a study of 45 patients randomized to either a voltage-escalating treatment regimen or to standard treatment [47]. Stone-free rates following one treatment session at 1month were 81% and 48% for the voltage-stepping and standard treatment groups, respectively. Renal injury was assessed by measurement of urinary microalbumin and β2-microglobulin levels, and both were shown to be lower at 1 week post ESWL in the voltage escalation group, suggesting a degree of reduced renal injury. Also recently, Honey *et al*. investigated the effect of delayed voltage escalation (starting with 1500 shocks at a fixed voltage and then stepping up to a set maximum) to

immediate voltage escalation (increase of 1 kV per 10 shocks up to a set maximum) in their randomized study of 160 patients with renal stones. The authors were unable to demonstrate any benefit in stone fragmentation with the delayed escalation technique, which in fact was shown to be inferior [48].

In a small prospective study of 50 patients undergoing ESWL for renal and ureteral calculi, Demirci *et al*. demonstrated a higher stone-free rate at 8 weeks follow-up for patients randomized to a voltage-stepping technique compared to those treated with constant output voltage (80% vs 60%), although this was not statistically significant [49]. Further work needs to be done in order to define an optimal treatment algorithm incorporating starting shock-wave voltage, voltage stepping (immediate or delayed), and shock-wave rate.

Effect of ureteric stenting

Rationale for use

ESWL has traditionally been considered as a challenge for treating impacted upper ureteric calculi, which are more difficult to fragment compared to stones in the renal pelvis. This effect may be explained by the previously mentioned physics of stone fragmentation. As a stone–water (i.e. urine) interface allows spallation and cavitation, stones impacted in the ureteral mucosa have reduced surface area in contact with water. Initially, it was almost routine that urologists would perform stenting prior to ESWL in order to increase the stone–water interface and thus improve stone fragmentation [24].

However, there is now substantial evidence suggesting that stenting prior to ESWL is unnecessary, and does not improve the rate or effect of stone clearance. Some studies have in fact demonstrated lower stone-free rates in stented patients compared with those who were not stented [50, 51].

The AUA Clinical Guideline Panel in 1997 and with the EUA in 2007 did not recommend routine stenting as part of ESWL treatment based on large meta-analyses of available data [17, 24]. A recent review of the literature by Haleblian *et al*. also did not recommend routine stenting prior to ESWL [52].

Very recently, Ghoneim *et al*. performed a prospective trial of 60 patients with obstructive proximal ureteric stones of 2 cm or less randomized to either stenting or nonstenting groups [22]. The authors demonstrated no significant difference in stone clearance, average number of sessions per patient, retreatment rates, and number of shock waves delivered. El-Assmy *et al*. also performed a study of 184 patients with ureteric stones of 2 cm or less in moderately or severely obstructed systems. The authors similarly were unable to demonstrate any advantage in the group randomized to stenting compared to the nonstented group [53]. However, many patients with stents complained of significant stent-related symptoms. Joshi *et al*. retrospectively reviewed outcomes of 82 patients with obstructing ureteric stones managed with percutaneous antegrade nephrostomy prior to ESWL, retrograde ureteric stenting prior to ESWL, and ESWL alone in the acute setting. They found urgent ESWL to be superior to antegrade or retrograde stenting prior to ESWL [54]. Although data are limited, other studies have also suggested that ESWL in the emergency or acute setting for obstructing ureteric stones is a safe and effective means of treatment [55, 56].

Stone manipulation prior to extracorporeal shock-wave lithotripsy

In the 1990s, the practice of pushing stones back into the renal pelvis from the proximal ureter prior to ESWL was widely accepted for uncomplicated calculi. However, in a large study of over 1700 patients, Cass *et al*. demonstrated that such stone manipulation gained little advantage over ESWL treatment of *in situ* proximal ureteric stones [57]. Danuser *et al*. also reported a similar finding in their prospective trial of 110 patients randomized to either *in situ* ESWL treatment or manipulation prior to ESWL [58]. More recently, Varkarakis *et al*. performed a similar randomized trial of 130 patients, but also analyzed financial costs of stone manipulation prior to ESWL. The authors found that although stone-free rates at 1 month were higher in the stone manipulation group, both groups were equal in this regard at 3 months post treatment [59]. Furthermore, the disparity in cost difference was mitigated by extra ESWL sessions required for the *in situ* treatment group, as well as more frequent follow-up and emergency room visits due to the longer times required for stone clearance.

Stent-related morbidity

The potential for significant stent-related discomfort and morbidity has been well-documented when used prior to ESWL [22, 52, 60]. Such symptoms include suprapubic pain, flank pain, dysuria, urinary frequency, and hematuria. Ureteral stents are also associated with bacterial colonization and an increased incidence of urinary tract infections, as well as being prone to encrustation and migration [61–63]. However, despite increased irritative symptoms, there is potential for decreased hospital readmissions and emergency room visits in these patients [60].

The insertion of a stent is also an invasive procedure and can be technically difficult with the inherent risk of ureteral perforation. Increased costs to the patient, such as analgesia or anticholinergics, as well as to treating

institutions, such as readmissions for cystoscopic stent removal, can also be significant [64, 65].

Latest developments in stent technology

In recent years, there have been several advances in minimizing the discomfort and morbidity associated with ureteral stenting prior to ESWL of ureteric calculi. Such advances have included the use of novel biomaterials, stent coatings, and drug-eluting technologies to reduce the risk of stone encrustation and infection [66–69]. Other advances have been in minimizing stent-related discomfort, such as intravesical instillation of ketorolac immediately after stent insertion [70]. However, ongoing research is required to show whether these advances will prove consistently superior to currently available stenting techniques.

Patient positioning

Shock waves delivered to ureteric stones may be impeded by the skeletal structure. With a patient in a supine position, transverse processes of vertebrae can occasionally impede shock waves to proximal ureteric stones. For mid-ureteral and distal ureteric stones the pelvic bones can significantly interfere with stone localization and delivery of shock waves, and a prone position for such stones may reduce this problem [71]. Several studies have been performed to improve stone fragmentation by way of altering patient position.

In 2006, Hara *et al*. performed a large study of 734 patients assessing the effect of rotated-supine positions for proximal stones and rotated-prone positions for mid and distal ureteric stones. Although success rates were equal, patients with proximal stones received fewer ESWL sessions and were able to tolerate greater shock-wave intensity when in the rotated-supine position [72]. For stones in the mid or distal ureteric positions, significantly improved stone-free rates were seen in patients treated in the rotated-prone position (Figure 52.2). Similarly Kose *et al*. demonstrated that a "modified prone position" for prevesical stones could significantly improve stone clearance (97.5%) compared to treatment in a standard prone position (89.9%), requiring fewer shock waves to be delivered and fewer repeat ESWL sessions (Figure 52.3) [73]. In their large series of patients treated successfully with ESWL, Tiselius treated 88% of patients with mid-ureteric calculi in the prone position (and 80% of patients requiring retreatment) to achieve an overall stone-free rate of 97.8% [18].

Despite latest generation lithotripters allowing shock-wave treatment with reduced analgesic requirements and light sedation, many urologists prefer ESWL to be performed under general anesthesia. Patients under light sedation are more prone to movement, e.g. due to pain, thus reducing the efficiency of shock-wave fragmentation, which requires effective coupling and the stone to remain at the focal point.

Patient factors

Obesity

Several studies have demonstrated that obese patients, as distinguished by body mass index (BMI), suffer from poorer stone-free rates post ESWL [74, 75]. Increased skin–stone distance can reduce the effectiveness of ESWL, and various aids and techniques may be required to allow stones in obese patients to reach the focal zone of the lithotripter [76, 77]. In a retrospective study of 111 patients with renal calculi, Perks *et al*. demonstrated that a skin–stone distance of 9.0 cm or greater (Figure 52.4) negatively impacted the success of ESWL (79% vs 57%) on their multivariate analysis, independent of stone size, location, and BMI [32].

Sex

The use of ESWL in women of childbearing age has been questioned, due to the ionizing radiation associated with fluoroscopy and the potential effects of shock-wave impulses on ovaries, especially when ESWL is applied to distal ureteric calculi which are within close proximity. Some animal studies have been performed to assess this effect, but have failed to demonstrate any association between ESWL to distal ureteric calculi and reduced ovarian function and fertility [78, 79]. Furthermore, limited small retrospective studies of women of childbearing age, who had previously undergone ESWL, have also failed to demonstrate evidence of fertility problems [80, 81]. Thus, given the lack of high-quality evidence, there are no current recommendations against performing ESWL on women of reproductive age [17].

In men, ESWL to distal ureteric calculi and its effect on gonadal function has also been assessed to a limited extent. One animal study with ESWL aimed at testes of male rats showed temporary histologic changes, but no difference in testicular function, as measured by successful mating with female rats and endocrine measures [82]. Several prospective human studies have been performed comparing spermatic function in men receiving ESWL for distal ureteric calculi to a control group consisting of men with renal or proximal ureteric calculi receiving ESWL. Sperm count and motility have been shown to be reduced post ESWL for distal ureteric calculi, but return to normal values by 3 months [83, 84]. However, one study demonstrated values to be within normal range at 3 months, but still remain lower when compared to baseline and the control group [85]. No

studies have been performed to assess the long-term effect of ESWL on testicular function, but this may be difficult to achieve as infertility can be multifactorial. Again, given the lack of high-quality evidence, men with distal ureteric calculi can be considered safe to treat with ESWL, but other methods such as ureteroscopic stone extraction may be preferable in men with intentions towards conception in the near term post treatment.

Medical factors

Adjunctive medical therapy

Calcium channel blockers and steroids have previously been used to reduce ureteral muscular tone and to decrease mucosal inflammation. Studies of the human ureter have revealed excitatory and inhibitory alpha-adrenergic receptors, with a predominance of alpha-1A and alpha-1D, especially in the lower ureter [86]. This explains the rationale for using alpha-1-adrenergic antagonists to decrease the force and frequency of ureteral contractions.

In recent years, several studies have evaluated the benefit of medical expulsive therapy (MET) with tamsulosin (selective alpha-1-adrenergic antagonist) in improving the passage of stone fragments post ESWL. Early in 2010, Hussein published results from a randomized controlled trial of 166 patients with renal stones. The group treated with tamsulosin and diclofenac had a significantly improved stone-free rate at 3 months (73%) compared to the group treated with diclofenac alone (55%) [87]. Time to stone stone clearance was also improved, with a difference seen at 1 and 2 months follow-up but not at 2 weeks. In 2008, Naja *et al*. demonstrated in a randomized trial of 139 patients with renal stones, earlier stone-free rates, fewer ESWL sessions, and reduced pain in the group treated with tamsulosin, as well as a trend for fewer cases of steinstrasse [88]. A prospective randomized double-blind controlled trial was performed by Bhagat *et al*. in 60 patients with renal and ureteral stones treated with ESWL. Despite small numbers, they demonstrated improved overall stone clearance with tamsulosin compared to controls (96.6% vs 79.3%), with a greater effect seen in larger stones greater than 10 mm [89]. All cases of steinstrasse resolved spontaneously in the treatment group, compared to 25% who required intervention in the control group. In a randomized nonplacebo trial with 55 patients, Agarwal *et al*. were able to demonstrate a significant increase in stone-free status after a single treatment of ESWL in patients treated with tamsulosin (55% vs 25%), despite the smaller power of the study [90]. However, no difference in pain control was seen.

Table 52.1 Summary of recommendations in the American Urological Association/European Urological Association Guideline for the Management of Ureteral Calculi [17].

- All patients with bacteriuria should be treated with appropriate antibiotics, and definitive stone treatment should be delayed until appropriate antibiotic therapy has been administered (level IV evidence).
- In patients with uncomplicated ureteral stones of less than 10 mm and whose symptoms are controlled, a period of observation with or without the use of medical expulsive therapy (MET) is an option (level Ia evidence):
  - These patients should be warned of any attendant risks of MET, such as drug side effects;
  - Such patients should have adequate pain control, absence of infection, and adequate baseline renal function;
  - Periodic follow-up imaging is required to monitor stone position and/or hydronephrosis.
  - Stone removal [e.g. extracorporeal shock-wave lithotripsy [ESWL] or ureteroscopy (URS)] is indicated in patients with failure of stone progression, persistent obstruction, and poorly controlled pain.
- In patients with ureteral stones greater than 10 mm, surgical treatment is generally required.
- For patients requiring surgical treatment for ureteral stones, both ESWL and URS are acceptable first-line treatments (level Ia evidence):
  - Patients must be informed of the available treatment options, expected outcomes, risks and benefits.
- Routine stenting is not recommended as part of ESWL treatment for ureteral calculi (level III evidence).
- Stone manipulation or push back into the renal pelvis is not necessary prior to ESWL, and the limited benefits may be outweighed by the morbidity and costs associated with stent insertion and its removal (level III evidence).

In 2009, a review of four MET trials by Schuler *et al*. supported the use of MET as an adjunct to ESWL, with the evidence showing benefits of tamsulosin and nifedipine over control groups [91]. Similarly, a review performed by Losek *et al*. of five prospective studies using tamsulosin as MET post ESWL for renal and ureteric calculi demonstrated improved stone clearance in two of the included studies (especially for stones >10 mm), as well as a reduction in painful episodes [92]. Conversely, Gravas *et al*. were unable to demonstrate greater stone clearance with tamsulosin in their nonplacebo randomized study of 61 patients, but a significant reduction in the use of nonsteroidal anti-inflammatory medication was found [93]. Very few side effects with tamsulosin were experienced by patients in the above studies, apart from ejaculatory dysfunction.

Contraindications

Despite proven safety in a wide variety of patients, several conditions preclude shock-wave treatment. These include bleeding disorders, pregnancy, congenital renal abnormalities, previous renal surgery, and the presence of concomitant urinary tract infection. Care should also be taken in patients with known impaired baseline renal function.

Clinical recommendations

In the last 5–10 years, there has been a significant increase in the data available addressing the efficacy of ESWL in the treatment of ureteral stones. Although several randomized trials have been performed comparing the efficacy of ESWL to URS stone extraction, there still remains a paucity of well-designed randomized controlled trials. Moreover, the heterogeneity in presenting stone-free rates, retreatment rates, additional procedures, complications, and costs has limited the analysis of the available data.

In 1997, the AUA undertook a large meta-analysis of largely single-arm studies and released guidelines on the management of ureteral stone disease [24]. In 2007, the AUA and EAU joined forces to develop the 2007 Guideline for the Management of Ureteral Calculi (Table 52.1) [17]. This meta-analysis of 244 randomized dual-arm studies and single-arm studies from various clinical series represents the largest, most recent and comprehensive review of available data on the management of ureteral calculi. Two significant changes were observed by the authors of this guideline.

The use of retrograde URS as a first-line treatment for middle and upper ureteral stones had increased significantly in the intervening decade. This can be attributed to the development of smaller caliber semi-rigid and flexible ureteroscopes, the introduction of improved endoscopic tools, such as the holmium : YAG laser, and the increased experience that urologists have of this procedure. Immediate and short-term complication rates, most notably ureteral perforation, have been reduced to below 5%, and long-term complications such as stricture formation occur in 2% or less of cases [94]. The 2007 AUA/EAU study showed overall stone-free rates are very high at 81–94%, depending on stone location, with the majority of patients being stone free after a single procedure [17]. Improved access to the proximal ureter with flexible URS permitted stone-free rates of up to 87% compared to 77% with semi-rigid URS, both of which are comparable to ESWL. Stone-free rates of 86% in the middle ureter were also demonstrated, which was not statistically superior to that seen with ESWL, but

follows similar trends to those seen in other randomized trials [20]. Despite the efficacy of URS, the associated need for ureteral stenting and its associated costs, discomfort, and morbidity to patients has biased patient and operator opinion towards ESWL in some cases.

The second notable change in ureteral stone management has been the establishment of MET in facilitating both spontaneous passage of stone, as well as stone fragments post ESWL. As part of the large AUA/EUA meta-analysis, the effectiveness was assessed of MET in accelerating spontaneous passage of ureteral stones and post ESWL fragments [17]. Likelihood of ureteral stone passage was found to be increased by 29% (statistically significant) when tamsulosin was used, compared to nifedipine which increased stone passage by 9% (not statistically significant) [17]. The added effect of corticosteroids was considered small, and thus single-agent therapy with an alpha-blocker currently is recommended.

Although ESWL has been proven to be a safe, well-tolerated, and minimally invasive means of managing renal and ureteral stones, some concerns still exist for the development of long-term complications, such as an increased risk of developing diabetes, hypertension, and impaired renal function. In 2006, Krambeck *et al.* analyzed 19-year follow-up data for 288 patients treated with ESWL for renal and proximal ureteric stones in 1985. Compared to matched controls with stones managed nonsurgically, they found an increased risk of hypertension (odds ratio 1.47), which was strongly related to bilateral treatment, and the development of diabetes mellitus (odds ratio 3.23), which correlated to number of administered shocks and treatment intensity [95]. The development of diabetes may be related to pancreatic islet cell damage from shock waves delivered for renal stones. There was no associated increased risk of development of renal insufficiency. However, in 2009, Makhlouf *et al*. demonstrated no increased incidence of diabetes at 6 years follow-up in their 1869 patients treated with ESWL, compared to matched controls from the National Health and Nutrition Examination Survey database [96]. Similarly, Sato *et al*. were unable to demonstrate an increased incidence of hypertension and diabetes in 772 patients with renal or ureteropelvic junction stones compared to 505 patients with ureteral stones, where follow-up was a minimum of 11 years [97]. In a series of 156 patients with solitary kidneys previously treated with ESWL, El-Assmy *et al*. demonstrated no significant effects on renal function or blood pressure [98]. However, long-term follow-up data were variable, with only 108 patients having follow-up longer than 12 months (range 1–16 years). Due to a paucity of quality long-term data, further large studies with long-term follow-up need to be performed before definitive conclusions can be made about ESWL and potential medical adverse effects.

Currently, there is a need for greater availability of nomograms or other models for predicting the success of ESWL treatment for ureteral and renal stones. Not only would this assist in choosing therapy that is most likely to be successful, but it would allow treating urologists to provide patients with valuable information in the informed consent process. In 2006, Kanao *et al*. performed a retrospective study of 435 patients with renal and ureteric stones in order to develop nomograms to predict stone-free rates at 3 months following single ESWL treatment. The authors found stone length, location, and number to be the most significant factors affecting outcome and adjusted their model accordingly (Table 52.2) [99]. CT imaging characteristics may also prove useful in developing predictive nomograms, by assessing the influence on successful treatment of

Table 52.2 Preoperative nomograms for predicting stone-free rate 3 months after single extracorporeal shock-wave lithotripsy (reproduced from Kanao *et al*. [99], with permission).

	Length (mm)				
	5 or less	6–10	11–15	16–20	21 or greater
Solitary stone					
Calyx	86.1 (68.7–96.2)	72.2 (60.8–81.6)	56.8 (40.0–70.2)	35.1 (21.7–51.6)	23.1 (10.7–37.0)
Renal pelvis	89.3 (97.7–73.6)	77.9 (64.1–88.5)	64.4 (48.4–77.0)	42.7 (23.5–61.4)	29.6 (11.1–49.6)
Proximal ureter	93.8 (86.0–98.3)	86.6 (80.9–91.3)	76.4 (65.2–84.5)	56.7 (36.6–73.3)	42.2 (18.8–63.9)
Mid-distal ureter	92.3 (80.7–98.3)	83.6 (89.7–76.8)	71.8 (59.1–82.2)	51.1 (29.3–71.0)	36.9 (15.9–60.0)
Multiple stones					
Calyx	71.2 (51.4–89.1)	49.7 (36.1–62.4)	33.5 (21.3–46.0)	17.4 (8.4–32.1)	10.5 (3.7–20.0)
Renal pelvis	76.8 (54.7–92.4)	57.6 (37.6–37.8)	41.1 (56.5–23.2)	22.7 (8.1–44.2)	14.3 (3.7–30.5)
Proximal ureter	85.5 (70.7–95.3)	70.8 (56.5–82.5)	55.2 (38.3–71.3)	34.0 (15.1–56.7)	22.5 (6.6–42.8)
Mid-distal ureter	82.4 (65.5–94.7)	65.8 (52.3–77.6)	49.5 (65.4–33.2)	29.2 (12.2–48.8)	18.9 (5.3–37.2)

Parentheses show 95% confidence intervals (%).

factors such as Hounsfield unit-assessed stone attenuation and skin–stone distance [31, 32].

The evidence-based guidelines detailed for the management of ureteric calculi by ESWL are consistent with the findings from an extensive review of the literature by the AUA/EUA Guideline Panel, as well as experience from the authorized groups involved in this review. However, such recommendations may not be applicable to all institutions, as clinical decision-making will need to account for availability of services and equipment, urologist experience and facility with various procedures, as well as costs to patients and hospitals. Furthermore, patient preference is becoming increasingly important in modern medicine, and all patients should be informed of the available procedures, expected outcomes, risks, and side effects to enable an informed decision on an appropriate treatment plan. To illustrate this point, several prospective trials comparing ESWL and URS have demonstrated higher satisfaction rates and patient preference for ESWL [15, 16, 100].

CHAPTER 53

Complications of Shock-Wave Lithotripsy

Fang Jann Lee & Yeh Hong Tan
Department of Urology, Singapore General Hospital, Singapore, Singapore

Introduction

It was in Munich, Germany, in 1980 that the first human trials on shock-wave lithotripsy (SWL) were undertaken for the treatment of upper urinary tract calculi [1]. Having demonstrated the reliability and reproducibility of this technology, the Dornier HM3 lithotripter subsequently gained US Food and Drug Administration approval in 1984. SWL rapidly became the treatment of choice for upper urinary calculi due in part to its non-invasive nature, wide application, patient endorsement, and cost-effectiveness [2]. The rapid adoption of SWL was also prompted by the belief the technology was safe with no significant acute or long-term adverse effects. A US cooperative study in 1986 concluded the technology was safe and effective when used to treat upper urinary calculi [3].

While there have been advances in percutaneous nephrolithotomy (PCNL) and retrograde ureteroscopic intrarenal surgery (RIRS) equipment and technique over the decades, SWL is still the choice for the treatment of up to 70% of uncomplicated upper tract calculi [4].

While early reports demonstrated SWL to be safe [1], there is growing awareness that the same shock wave that promotes stone fragmentation and disintegration also injures organs and tissue within the focal area, which can result in an adverse clinical outcome. Complications following SWL can result either from stone fragmentation or the effects of the shock wave on the adjacent tissue.

Complications related to stone fragments

Much of the morbidity associated with SWL treatment results from the fate of the fragmented calculi. SWL can result in incomplete stone fragmentation, residual calculi, steinstrasse, and ureteral obstruction. Several risk factors have been identified as predictors of poor stone clearance rates: stones of greater than 2 cm, stones within dependent or obstructed portions of the kidney, certain stone compositions (mostly calcium oxalate monohydrate and brushite), body habitus, and unsatisfactory targeting of stone [5].

Residual fragments

Newman *et al*. first introduced the concept of clinically insignificant residual fragments (CIRFs) after SWL: stone fragments smaller than 5 mm, not composed of struvite, in asymptomatic patients with sterile urine [6]. These are reported to be present in 12–30% of patients after SWL [7]. It has remained of concern whether CIRFs are really clinically insignificant. In prospective follow-up studies, 22–43% of patients with CIRFs subsequently became symptomatic and/or required intervention [7, 8].

Besides causing symptoms or requiring intervention, residual stone fragments are thought to act as a nidus for new stone formation and to accelerate stone growth. Stone recurrence rates are increased in patients with residual fragments compared to those rendered stone

Smith's Textbook of Endourology, Third Edition. Edited by Arthur D. Smith, Gopal H. Badlani, Glenn M. Preminger, Louis R. Kavoussi.

free [6]. Streem *et al*. reported in a prospective study of 160 cases that residual fragments of less than 4 mm after SWL were found to increase in size in 18%, decrease in 16%, and remain stable in 42% [7]. Aiming for a stone-free status is even more important in metabolic stone disease. A stone-free state reduces the risk of recurrence and also prolongs treatment interval.

Residual fragments from struvite stones can lead to post-SWL bacteriuria and recurrent and treatment-resistant urinary tract infection (UTI), and become a focus of septicemia.

Steinstrasse

Poor stone fragmentation can also result in ureteric obstruction. A steinstrasse (or stone street) is a term coined to describe a column of fragments obstructing the ureter (Figure 53.1). Coptcoat *et al*. proposed the following classification of steinstrasse: type I is made entirely of fragments of 2 mm or less; type II has a leading fragment of 4–5 mm and a tail of 2-mm fragments; and type III is composed of large fragments [9]. This classification was not widely applied in clinical practice, but the principle of diagnosis and treatment of steinstrasse as described in Coptcoat *et al*.'s 1988 article is still applicable to this day.

Madbouly *et al*. reported an overall incidence of steinstrasse at 3.97% in 4634 patients treated with SWL [10]. Multivariate analysis further identified stone size (>2 cm) and site (renal), renal morphology (dilated system), and shock-wave energy level (>22 kV) as significant risk factors for steinstrasse formation.

The majority of steinstrasse is short and will pass spontaneously, causing only mild discomfort. A larger and longer steinstrasse has the potential to produce partial or complete ureteral obstruction, pain, and secondary infection. Patients with larger steinstrasse require early recognition and prompt management to avoid symptom escalation and progression to sepsis. Acute renal failure and anuria can also complicate cases of bilateral SWL. Fedullo *et al*. reported that among his first 1000 patients undergoing SWL, 27% of those with persistent steinstrasse had silent obstruction on review [11]. This can lead to ipsilateral renal deterioration over time if not identified, and underscores the need for the urologist to closely follow-up patients with plain X-rays, ultrasound, and/or intravenous pyelogram (IVP) to rule out silent obstruction post SWL.

Steinstrasse can potentially be averted with the placement of an indwelling ureteral stent prior to SWL. In selected patients with stone burden exceeding 25 mm, pretreatment placement of ureteral stents reduces the

Figure 53.1 Steinstrasse (A) before and (B) after shock-wave lithotripsy.

overall complications and auxiliary procedure rates [12]. Placement of a ureteral stent initially allows passage of urine and gravel through and around it, respectively. With time, the stent induces passive dilation of the ureter and, upon removal, passage of larger fragments can occur through the distended ureter [13]. Fine *et al*. proposed that the urine reflux to the kidney facilitated by an indwelling stent also promotes ureteral peristalsis, which further helps propel urine and gravel into the bladder [14].

Routine pre-SWL ureteral stenting however, is associated with morbidity risks, including gross hematuria, infection, and pain. The degree of discomfort may necessitate removal of the stent [15]. Incidents of stent migration and obstruction are not uncommon [16]. In addition, pre-SWL stenting increases the cost of the procedure and the level of invasiveness [17].

Although ureteral stenting does not prevent steinstrasse or improve stone-free rates, it has a role in preventing obstruction from steinstrasse and should be considered in treating patients with stone size greater than 2 cm [17–19]. In treating stones of less than 20 mm in solitary kidneys, although ureteral stents are associated with more irritative symptoms, their use resulted in fewer hospital readmissions [20].

Infection

The overall reported incidence of sepsis following uncomplicated SWL is less than 1%, rising to 2.7% for staghorn stones [21]. This risk of sepsis is increased in the presence of bacteriuria prior to SWL and especially if there is distal obstruction [22]. The incidence of bacteremia has been reported in up to 14% after SWL [23]. Stone may harbor bacteria even if the urine is sterile [24]. Stone fragmentation can release viable bacteria and preformed bacterial endotoxins that enter the systemic circulation via the microvasculature disruption associated with SWL. Infective complications can include perinephric [25] and psoas [26] abscesses, candidal endophthalmitis [27], and military tuberculosis [28]. Death from sepsis has also been reported [29].

Bacteriuria can develop in 5–16% of patients undergoing SWL with a sterile preprocedure urine culture [30] and 2–3% of these cases will manifest as clinical UTI [30].

The use of periprocedure antibiotics remains controversial. Dincel *et al*. compared the relationship between different stone types and the incidence of UTI in patients undergoing SWL, and found a significantly higher risk of UTI in patients with struvite stones than in those with other types of stones (17.3% vs 2.1%) [31]. There was no significant correlation between the occurrence of bacteriuria and number of stones, size of stones, stone-free rate, or location of the calculi. The authors concluded that prophylactic antimicrobial treatment is only indicated if there is a history of UTI or if infection stone is suspected. Bierkins *et al*. in a prospectively randomized trial of prophylactic antibiotics versus placebo prior to SWL found no difference in the rate of developing post-procedure UTI between the arms (2–3%), and concluded that patients with sterile urine prior to SWL do not need antibiotic prophylaxis [32].

In a meta-analysis of the available literature, however, Pearle *et al*. concluded that a policy of antibiotic prophylaxis prior to SWL in patients with sterile pretreatment urine cultures is efficacious in reducing the rate of post-SWL UTIs (5.7% vs 2.1%). It is also cost-effective when the need for inpatient treatment of urosepsis and pyelonephritis is taken into consideration [33].

While the use of prophylactic antibiotics remains controversial, a good understanding of potential infective complications, coupled with strategies for treatment in the absence of obstruction and bacteriuria, will minimize infective morbidities.

Complications related to tissue injury

Mechanism of tissue injury in shock-wave lithotripsy

Two primary mechanisms have been postulated for SWL-induced tissue damage: cavitation [34] and shear stress [35, 36]. These are the exact same two mechanisms required for stone fragmentation. These SWL-induced tissue injuries are characterized by damage to the vascular endothelium and the rupture of small capillaries. Animal studies have identified several risk factors, including lithotripter parameters (number of shock waves, output energy, pulse repetition rate), and kidney parameters (pediatric or elderly patients, solitary kidney, renal infection, pre-existing hypertension) [37, 38]. In addition, ischemic-reperfusion damage from free radical release after SWL has also been shown in animal studies [39, 40], and this may also contribute to tissue injury.

Acute renal complication

With better understanding of the mechanism of SWL, it is now known that SWL induces acute structural changes to the renal anatomy in most cases. Radiologic changes have been detected using ultrasound, computed tomography (CT), magnetic resonance imaging (MRI), and quantitative radionuclide renography in 63–85% of patients within 24 h following treatment with an unmodified HM3 lithotripter [41–44]. Radiologic changes included perinephric hematoma (Figure 53.2), renal enlargement, renal fracture, and loss of corticomedullary junction demarcation. Renal/perirenal

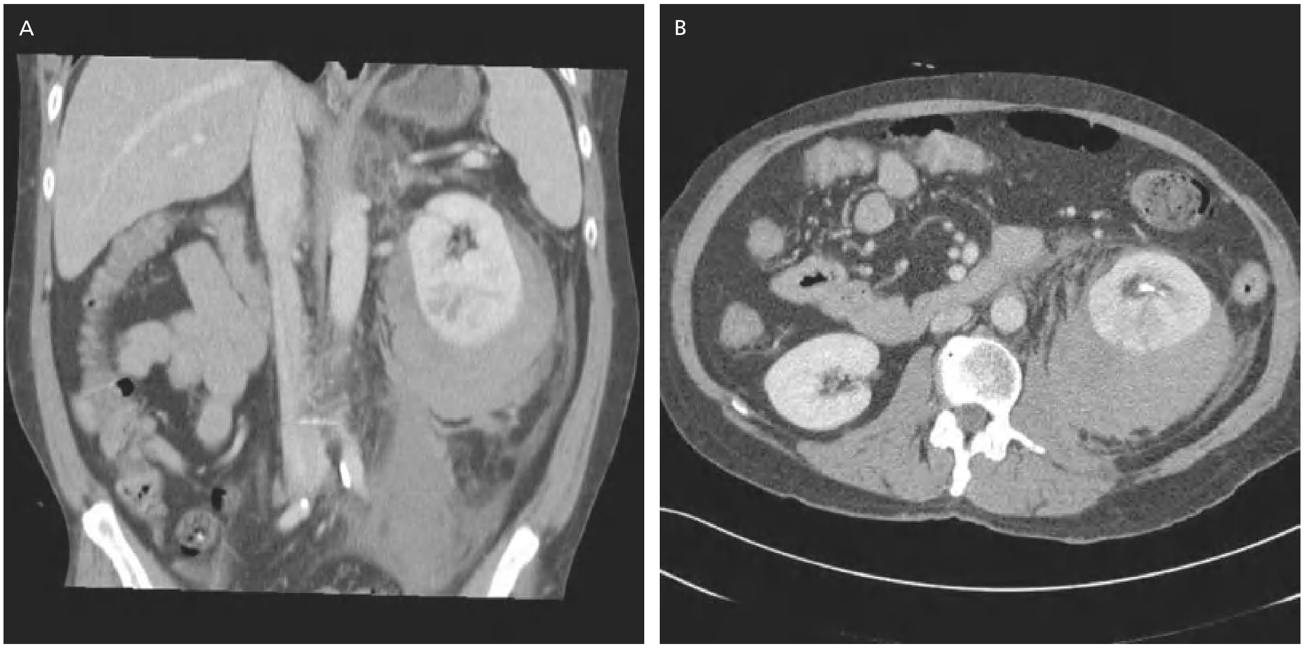

Figure 53.2 (A, B) Post-shock-wave lithotripsy perinephric hematoma.

hematoma and edema are the most common findings. Among the modalities, MRI and CT have proven to be more sensitive than ultrasonography in identifying the post-SWL changes [42].

Bleeding

Hematuria is one of the most common clinical manifestations of post-SWL renal injury. It is observed in patients receiving more than 2000 shocks, is usually of no clinical significance, and can be expected to resolve within 12 h [1, 41]. Petechial bleeding of the skin has been noted in about 10% of patients, while perirenal and subcapsular fluid collection can be detected in 24–32% of patients following SWL [41, 42, 44]. Clinically apparent perirenal hematomas may be expected following 0.6% of SWL treatments [45]. Knapp *et al*. noted that patients with a history of hypertension, particularly those with unsatisfactory control of hypertension, were at increased risk for the development of perinephric hematomas following SWL [42]. Patients on antiplatelet agents were also at increased risk [46]. Other vascular-related risk factors identified include diabetes mellitus, coronary artery disease, and obesity [47]. Age is also a risk factor, with incidence increasing two-fold for every 10 years [48]. Severe cases of hematoma formation can result in irreversible acute renal failure.

Most hematomas can be managed conservatively. Rarely is there a need for blood transfusion or surgical drainage/evacuation for persistent hemorrhage or mass effect. Although some hematomas can persist for months or years, most will resolve within weeks with no long-term sequelae [49].

Acute nonrenal complications

Gastrointestinal injury

Reports on the effect of SWL on the gastrointestinal tract have been few and widely debated. Chaussy *et al*.'s early experience with SWL revealed no injury to isolated intra-abdominal organs [50], including the bowels. It was assumed that shock waves had minimal effect on tissue as they passed through the body [1].

Since then, case studies have reported isolated instances of gastrointestinal perforations [51, 52], ureterocolic fistulas [53], and even a case of gastrointestinal anastomotic dehiscence [54]. A review of the available literature reported the overall incidence of gastrointestinal complications following SWL to be 1.81% [55].

Several cases of clinical pancreatitis have also been observed, along with cases with asymptomatic rises in serum amylase and lactate dehydrogenase levels following SWL [3, 56]. Coptcoat *et al*. reported their experience with 600 consecutive cases of SWL and noted a 10% incidence of prolonged post-SWL ileus requiring intravenous hydration for more than 24 h [57].

Al Karawi *et al*. prospectively studied 40 patients following SWL and revealed gastric and/or duodenal erosions in 80% of them [58]. Sixty percent of the erosions were in the proximal part of the stomach. None resulted in clinical gastrointestinal bleeding. The authors

postulated that the larger air–tissue interface and the resultant increased energy dispersal at this interface can account for the high incidence of erosion.

Splenic rupture has also been reported post SWL [59–61].

Cardiovascular complications

Cardiac arrhythmia was a well-described complication following SWL with the first-generation spark plug lithotripters. To overcome this, electrocardiogram (ECG)-triggered, gated SWL was recommended. The reported frequency of dysarrhythmia following ECG-triggered gated SWL with the first-generation lithotripters ranged from 0.3% to 1% [57, 62]. With the later generations of lithotripters utilizing piezoelectric or electromagnetic sources, general anesthesia was no longer necessary and thus nor was continuous ECG monitoring. Fixed-rate shock-wave administration was proposed to be a reasonable option for the treatment of urolithiasis with the later-generation lithotripters, such as the Dornier MFL 5000 lithotripter [63].

Initial experience with piezoelectric lithotriptors found only occasional episodes of dysarrhythmia without ECG triggering [64, 65]. With continuous ECG monitoring, cardiac dysarrhythmia were noted in 20–54% of treated patients [66, 67]. Ungated SWL can be performed but the incidence of cardiac dysarrhythmia increases [68]. Zanetti *et al*. found no significant correlation between the occurrence of dysarrhythmia, the side treated, the number and strength of the shock waves, or the administration of analgesics [69]. Most, if not all. cases can be completed with gating when symptomatic dysarrhythmia occurs. While ungated SWL appears safe, ECG monitoring is still advisable during the procedure in view of the high incidence of dysarrhythmia, as it will allow immediate corrective measures to be instituted as required.

Patients with cardiac pacemakers can undergo SWL, but depending on the type of pacemaker, reprogramming may be necessary [70, 71]. Rate-responsive pacemakers should be programmed to the nonrate-responsive (VVI) mode, and the pacemaker should be at least 5 cm from the blast path. Urologists who treat patients with a pacemaker are advised to obtain clearance for the patients from their attending cardiologist, and have on standby corrective equipment or temporary pacemakers.

There have been occasional reports of aortic aneurysm rupture during SWL [72–74] and rare reports of major venous thrombosis following SWL [75, 76]. Some authors in small studies have demonstrated that SWL can be performed safely in patients with abdominal aortic aneurysms and renal artery aneurysms [77–79], but the issue remains controversial.

Fertility and pregnancy

Evidence from experimental and animal studies have found that SWL has no significant permanent effect on testicular and ovarian function [80, 81]. Pregnancy, however, is an absolute contraindication for SWL. Shock waves lead to fetal damage and death in the late stage of pregnancy in mice [82]. Following inadvertent application of SWL in pregnancy, there have been case reports of successful delivery of babies with no abnormality [83], but these findings do not justify clinical use of SWLin pregnancy [84].

Andreessen *et al*. studied the semen of healthy men post SWL for distal ureteric stone and found a transient reduction in sperm density and motility that recovered after 3 months [85].

Long-term complications

Renal function

The risk of long-term renal deterioration after SWL is a real concern that has been much debated. The renal histologic manifestation post SWL has been well-documented in animal studies. Newman *et al*. reported diffuse interstitial fibrosis, focal calcification, nephron loss, and scar formation in canine kidneys 1 month post SWL [86]. Morris *et al*. demonstrated a correlation between number of shock waves and the size of the resulting scar [87]. In contrast, Chaussy *et al*. reported no histologic abnormality in canine kidneys up to 1 year post SWL [88].

Functional study in humans showed a reduction of glomerular filtration rate (GFR) shortly after SWL, but this normalized after several weeks [89]. However, long-term decline in GFR after SWL has been shown in patients with underlying renal insufficiency (serum creatinine >2 mg/dL) or with a solitary kidney [90, 91]. Evan *et al*. showed that in pigs, existing pyelonephritis potentiates the functional changes induced by SWL [92].

Pienkny *et al*. established the safety of bilateral SWL when they followed up 319 patients with simultaneous SWL for 3.2 years and found no clinical difference in serum creatinine level when compared to a group of 41 patients who underwent staged bilateral SWL [93]. This result was supported by Perry *et al*. who followed up 120 patients with bilateral SWL for 21 months and found no significant change in serum creatinine level from pre-treatment level [94].

Liou *et al*. compared 83 patients with a solitary kidney treated with SWL, PCNL, or both for a mean of 4.4 years and found stable renal function between the treatment groups. This implied that both therapies are equally efficacious for preserving renal function when performed in patients with a solitary kidney [95]. Caution,

however, is needed in interpreting studies that rely on serum creatinine to estimate renal function status as up to 20% of renal function can be lost without a significant change in the serum creatinine level.

Hypertension

An early retrospective study by Lingeman *et al*. reported that 8.2% of 243 patients treated with SWL were hypertensive on follow-up and required antihypertensive treatment [96]. The mean follow-up was 1.5 years, giving an annual incidence of 5.5%. However, this does not differ much from the 6% incidence of new-onset hypertension in the general population aged between 30 and 60 years old [97]. Also, further retrospective studies by other authors did not reproduce this correlation [97, 98].

To further investigate the association of SWL with hypertension, Lingeman *et al*. retrospectively studied 961 patients treated for stone disease, of whom 80% were treated with SWL. The remainder were treated with either ureteroscopy or percutaneous surgery, and served as the control. The annual incidence of hypertension in the SWL group(2.4%) did not differ significantly from that in the control group (4.0%) [99]. There was, however, a significant rise in the diastolic blood pressure (DBP) in the SWL group, a finding collaborated by Yokoyama *et al*. [100] Lingeman *et al*. then followed up with another set of blood pressure measurements at 4 years post treatment; the results still showed no significant difference in the annual rate of new-onset hypertension in the SWL arm (2.1%) compared to the control arm (1.6%). The DBP remained significantly higher in the SWL arm but with a trend towards baseline in the later years of the follow-up period [101].

The association of SWL with hypertension has also been studied prospectively. Knapp *et al*. studied the changes in the intrarenal vascular resistive index (RI) using Doppler ultrasound and found an increase in the RI in 30% immediately post SWL [102]. When followed up for 3 months, they found a significant and age-dependent increase in the RI in the treated kidney [103]. Of the patients with a post-SWL RI greater than 0.690, 39% developed hypertension. Those with an RI greater than 0.690 showed a 0.8 sensitivity and a 0.7 specificity in predicting arterial hypertension. The authors suggested that RI is useful to identify the high-risk group for arterial hypertension after SWL. Patients aged over 60 years may develop hypertension at a higher rate. Janetschek *et al*. noted a 45% incidence of developing new-onset hypertension in the group over 60 years old when evaluated for post-SWL changes in RI [104].

A recent study from the Mayo Clinic (Rochester, MN, USA) reviewed the charts of 630 patients at 19 years post SWL. When matched for age, sex, and year of presentation, the SWL-treated patients were found to be 1.5 times more likely to develop hypertension than controls who were conservatively managed for urolithiasis [105]. This risk was highest for those treated with bilateral SWL.

Challenges in evaluating the association of SWL with hypertension include difficulty in identifying if the hypertension is the result of the stones, the renal disease resulting in the stone, or the effects of the treatment to remove the stones. Researchers have found that stone formers have higher blood pressure than controls drawn from the general population and matched for age, sex, and ethnic origin [106].

In summary, no randomized controlled study has yet demonstrated a causal relationship between SWL and hypertension. The true cause of hypertension post SWL is probably multifactorial with the renin–angiotensin system playing a part in its development.

Diabetes mellitus

Krambeck *et al*.'s 19-year retrospective review of the long-term safety of SWL also found that SWL-treated patients were over three times more likely to develop diabetes than controls. Of note, these patients were treated with an unmodified Dornier HM3 back in 1985. The risk of developing diabetes was related to the average intensity and number of shocks administered. There was no association with patient's body mass index (BMI) [105]. These findings have yet to be confirmed by other authors. Sato *et al*. performed a similar study but found no increase in incidence of hypertension and diabetes [107].

It was hypothesized that diabetes mellitus resulted from pancreatic collateral injury during SWL. Reports of acute pancreatitis following SWL seem to support this. However, a follow-up study on patients with SWL for pancreatic stones did not provide evidence to support this idea [108]. A prospective study of possible acute endocrine pancreatic injury following SWL of upper tract stones with a third-generation electromagnetic lithotripter by measuring serum pancreatic markers at 24 h also did not detect any acute changes [109]. No conclusions can be made at this point without further long-term prospective study.

Conclusions

SWL remains arguably the safest available surgical modality for treatment of urinary calculi. Although energy required for stone fragmentation can result in surrounding tissue injury, serious acute adverse events are rare, depending on the individual patient's risk factors, lithotripter used, and treatment protocol administered. Long-term complications of SWL are currently still controversial and future prospective studies will hopefully provide the answer in the near future.

SECTION 5
Stone Management in Urology

CHAPTER 54
Natural History of Stones

Michael G. Santomauro & Brian K. Auge
Department of Urology, Naval Medical Center San Diego, San Diego, CA, USA

Introduction

Nephrolithiasis is a common problem in the USA and the incidence is increasing; approximately 13% of men and 7% of women in the USA will be diagnosed with a kidney stone at some point [1]. The true prevalence of stone disease is probably underestimated because many stones remain asymptomatic and consequently go undiagnosed [1]. Despite the variety of preventive medical management and intervention tools, nephrolithiasis is largely a recurrent disease with a relapse rate of approximately 50% in 5–10 years and 75% in 20 years [2]

As the prevalence of urolithiasis is increasing, the financial burden appears to be escalating. The economic impact of urolithiasis takes into account not only the direct medical cost of treatment, but also the indirect cost associated with lost work days. The cost of urolithiasis is estimated at nearly US$2 billion annually, representing a 50% increase since 1994 [1]. Given this outlook, a diagnosis of kidney stones has a substantial impact with regard to patient morbidity and healthcare dollars [1].

Pathogenesis of stone formation

Although much is understood about the physical chemistry involved in nephrolithiasis, the inciting factor and sequence of events that lead to the formation of a kidney stone remain elusive. The vast majority of patients are idiopathic calcium oxalate (CaOx) stone formers (accounting for >80% of stones), making this group critical to the understanding of the pathogenesis of nephrolithiasis [3]. Figure 54.1 provides a gross overview of the initiation of stone formation.

At the molecular level, the first step in stone formation is by a process called nucleation, which occurs at a critical level of super saturation. As the crystals form a lattice structure and begin to grow, they unite to form larger stone structures [3]. This evolving concentration cascade of crystallizable substances in stone formation can be described by defining zones of saturation (Table 54.1).

At the macro level, the leading theory to explain the growth of stones is the formation of a Randall's plaque, which is an area of plaque that acts as an ideal site for overgrowth of CaOx to develop into a calculus. To support this theory, Matlaga *et al.* investigated the prevalence of attached stones in CaOx stone formers [4]. In 23 patients, 24 kidneys and 172 renal papillae were examined. Attached renal calculi were detected in 50% of the papillae, and plaque was present in 91% of the papillae examined. Following removal of CaOx stone at the tip of a renal papilla, a significant amount of plaque was observed at the site of the attachment. The finding that half of the CaOx stone formers harbored attached renal calculi supports the hypothesis that the attached stone is an instrumental component in the formation of CaOx stones [4]. Additionally, Kuo *et al.* reported on a series of renal papillary and cortical biopsies at the time of percutaneous nephrolithotomy (PCNL) in a series of stone formers, in which their histologic data provided similar supportive findings for the role of Randall's

Smith's Textbook of Endourology, Third Edition. Edited by Arthur D. Smith, Gopal H. Badlani, Glenn M. Preminger, Louis R. Kavoussi.

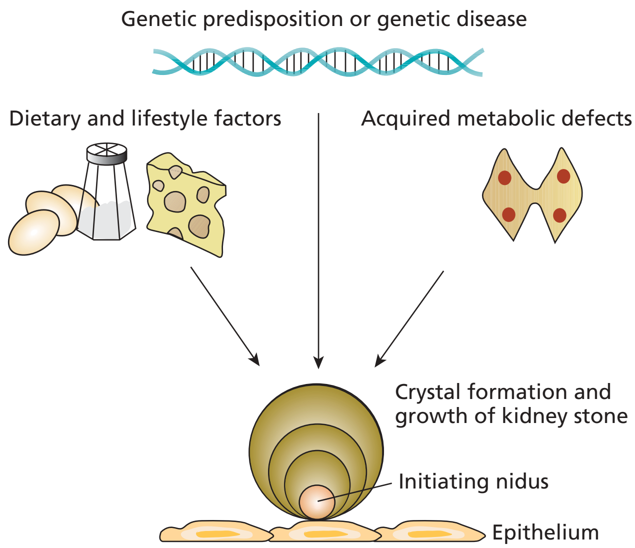

Figure 54.1 Pathogenesis of kidney stones. Using calcium oxalate stones as a model, three categories of factors (genetic, metabolic, and dietary) act in conjunction or in isolation to lead to kidney stone formation. The process needs an initiating nidus on the epithelium, which provides the platform for crystallization and growth (reproduced from Moe [2], with permission).

Table 54.1 Physical chemistry of stone formation (reproduced from Miller *et al*. [3], with permission).

Zones of urinary saturation	
↑	Spontaneous crystal formation occurs Crystals already present may grow Aggregation more likely
Increasing concentrations of crystallizable substances	**Formation product**
	No spontaneous crystal formation Crystals already present may grow Epitaxial growth and aggregation possible
	Solubility product
	Undersaturated No nucleation or growth Dissolution may occur Aggregation possible

plaque in the pathogenesis of stone disease [5]. Figure 54.2 displays the stepwise relationship and interplay among the various factors in creating a stone.

Even though there is a litany of information to support stone formation based on molecular saturation levels in conjunction with both inhibitor and promoter components at different rates, there is a paucity of literature that delineates how quickly these stones grow based on their composition. An interplay exists between many variables that both promote and inhibit stone formation, including renal function, hydration status, diet, saturation coefficients of suspended particles, previous stone history, and urinary constituents and their concentrations. These entities make predictions of stone growth very difficult to ascertain as many assumptions are made even in mathematical modeling. Of all the different types of stones, it appears that struvite stones, based on their infectious nature, form more rapidly compared to patients diagnosed with other types of stones such as CaOx stones.

Imaging

Besides studying the formation of stones, there are studies attempting to use the differences in radiodensity or Hounsfield units (HU) within noncontrast computed tomography (CT) imaging to assist in defining the chemical make-up of stones [6]. Knowing the composition of a urinary calculus can be a key factor in the appropriate management. It may help decide whether the urine should be alkalinized, especially if the stone appears to be a uric acid stone, or if the stone will be amenable to extracorporeal shock-wave lithotripsy (ESWL), or whether PCNL or ureteroscopy (URS) should be considered. However, when the HU values of calcium, uric acid, struvite, and cystine stones were compared, the overlap of ranges precluded accurate identification as the mean values were not significantly different from one another [6]. Early CT studies using a single energy technique attempted to show that the attenuation of stones in CT may provide some information about their composition, but they were only able to distinguish some but not all urinary stones. They concluded that the considerable overlap of attenuation values in single-source CT precluded an accurate differentiation of stones according to their different compositions, and therefore was not helpful in determining the most appropriate treatment modality [6–9]. Motley *et al*. assessed over 100 stone patients on preoperative work-up with conventional noncontrast CT scan imagery and compared the results to the final stone analysis. They noted that the largest difference in HU in separate stone entities was between the mean HU density of calcium (105 ± 43) and uric acid (50 ± 24) stones, with considerable overlap when comparing other varieties of stone [6].

Recently, the dual-energy source CT scanner has been introduced as a possible tool to help delineate stone

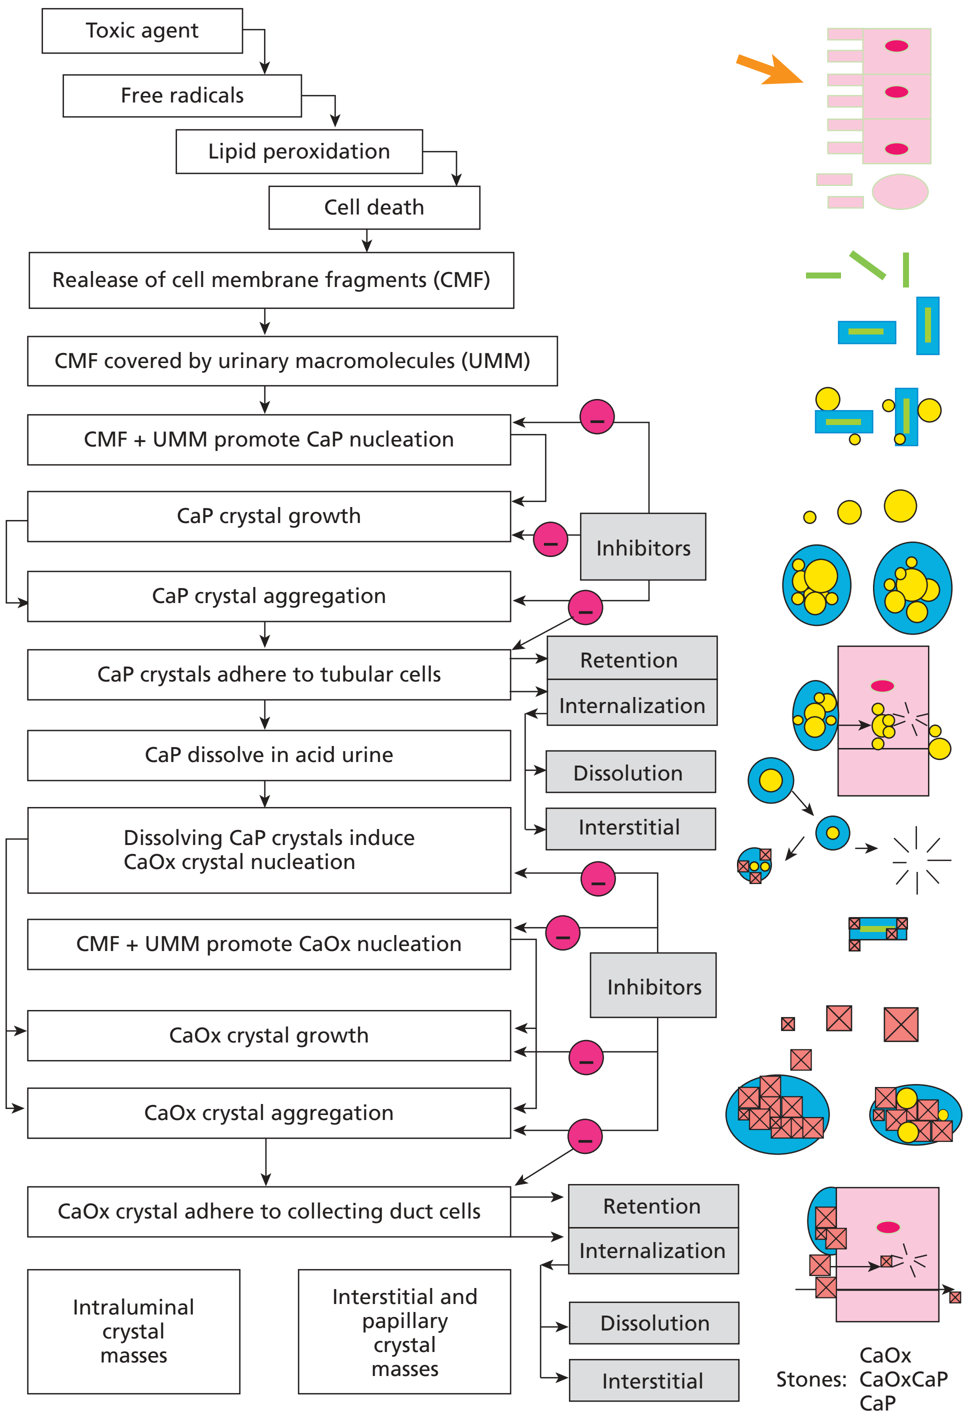

Figure 54.2 Stone formation. There is nucleation of crystals by destroyed proximal tubular cells, initiated by lipid peroxidation by free radicals. Next, if there is a deficient activity or concentration of macromolecules that inhibits crystallization, larger crystals form and adhere to tubular walls. Large crystals are then unable to be broken up by macrophages, thus providing a crystal surface for subsequent stone formation on the papillary tip. CaP, calcium phosphate; CaOx, calcium oxalate (reproduced from Tiselius, H.G.. Epidemiology and medical management of stone disease. *BJU Int* 2003;91:758–767, with permission).

composition [10–13]. In assessing the differentiation between uric acid (UA)-containing and non-UA-containing urinary stones, 40 urinary stones were evaluated and analysis indicated that dual-energy CT correctly identified 100% of UA-containing stones, showing that dual-energy CT allows for accurate differentiation between UA-containing and non-UA-containing stones [10]. Using a dual-source CT scan in patients with a history of stones adds an additional tool to the arsenal in treating these patients as the imaging can discriminate between UA stones and other types.

In regards to following patients for postoperative stone-free status, various imaging modalities have been utilized, including ultrasound, plain X-ray, and CT scan. Currently, an unenhanced helical CT is the imaging technique of choice as it has demonstrated a sensitivity of close to 100% and specificity of around 90% in the detection of calculi. Because renal colic frequently affects young adults, with a rate of recurrence of almost 50%, the systematic use of CT at a patient's presentation raises an ethical concern about the repeated doses of radiation being administered [14]. The amount of radiation received during a single noncontrast CT of the abdomen and pelvis during stone evaluation is estimated to result in fatal malignancies in 1 in 1000 patients [15–17].

A single noncontrast CT of the abdomen and pelvis may expose a patient to 20 mSv of radiation. It is estimated that a total of three noncontrast CTs would be approximately equivalent to the radiation exposure of an atomic bomb survivor within 3 km of detonation [15]. Table 54.2 shows comparisons of various radiation exposures due to diagnostic imaging and other environmental sources. One study sought to determine the impact of a low-dose CT protocol (30 mAs) on approximately 125 patients and compared these data to the information obtained with a standard protocol (180 mAs). In patients with a body mass index (BMI) of less than 30, low-dose CT achieved 95% sensitivity and 97% specificity for detecting ureteral calculi. When considering stone size, low-dose CT was 86% sensitive for identifying ureteral calculi of less than 3 mm and 100% sensitive for detecting calculi greater than 3 mm [14]. Recently, ultra low-dose and conventional CT protocols have been investigated for detecting distal ureteral calculi in a cadaveric model [15]. A total of 85 CaOx stones 3–7 mm long were prospectively placed in 14 human cadaveric distal ureters in 56 random configurations. In a study comparing mAs settings at 140 mAs (conventional CT) with 7.5 mAs, the group found that the sensitivity and specificity in detecting ureteral calculi were similar, but with the latter setting the radiation dose was decreased by up to 95% and thus it reduces the risk of long-term secondary malignancies. Table 54.3 shows the radiation doses and exposure reduction at various CT scan settings.

To minimize radiation, physicians have utilized other modalities such as ultrasound. Ultrasound clearly has its limitations. Even though the sensitivity in diagnosing calyceal dilation and ureteral dilation is approximately 73%, in diagnosing a ureteral stone it approaches 19% [18].

Environmental factors

Even though the theory of stone formation and varying imaging modalities is important, a substantial propor-

Table 54.2 Radiation exposure due to diagnostic imaging and other environmental sources (reproduced from Jellison *et al.* [15], with permission).

Diagnostic procedure	Typical effective dose (mSv)	Number of chest X-rays* for equivalent effective dose
Chest X-ray*	0.02	1
New York–London round-trip flight	0.2	5
KUB	0.7–0.9	35–45
Mammogram	3	150

Setting (mAs)	Equivalent dose (mSv)	Radiation decrease (%)
140	19	0
100	13	–32
60	8	–58
30	4	–79
15	2	–89
7.5	0.95	–95

tion of the risk factors for nephrolithiasis stems from environmental factors. Of these factors, dietary modification assumes a pivotal and first-line role in treatment, and diet is a subject of much interest in its relation to urinary lithogenesis [19]. The efficacy of dietary regimens has been confirmed by examining the endpoints of urinary chemistry, stone recurrence, or both. Even in instances where there are no prospective trials, some of the physiologic data are strong enough to justify therapeutic recommendations. The dietary components that can be manipulated include intake of fluid, sodium, animal protein, fruits, calcium, and oxalate. Additionally, Borghi *et al.* conducted a randomized trial where they noted a 45% reduction in stone incidence in patients managed with an increase in fluid consumption alone at 5-year follow-up [19, 20].

When dietary modification is ineffective, pharmacologic treatment should be contemplated [2].One example of medical treatment includes the use of potassium citrate. By providing an alkali load, potassium citrate increases urinary pH and citrate, thereby increasing inhibitory activity [21]. The data in favor of citrate supplementation, based on the known effects of citrate to lower the super saturation of calcium salts and inhibit crystal growth and aggregation, remain quite favorable. One randomized trial of potassium citrate supplementation in patients with hypocitraturia demonstrated a reduction in stone recurrence rates of 75% compared to placebo [22]. In a second trial, 64 patients were randomly assigned to receive placebo or potassium–magnesium citrate daily for up to 3 years in a double-blinded design. New calculi formed in 63.6% of subjects receiving placebo and in 12.9% of subjects receiving potassium–magnesium citrate [19].

Stone passage

Many patients with renal calculi will inevitably present to the urologist's clinic symptom free, at which time an observational or "expectant" strategy is often employed [23]. As technology has improved, unenhanced helical CT is used almost exclusively for the diagnosis and treatment of patients with acute ureterolithiasis [24]. When diagnosed, stone size as measured by axial diameter and location within the ureter are suggested to be the most important factors used to predict the likelihood of spontaneous passage [24].

Once diagnosed, it has been shown that asymptomatic stones that pass spontaneously will likely do so early, with about 30% of stones passing in 2 years and decreased passage rates during subsequent years [25]. In regards to time for symptomatic stone passage, the majority of stones pass spontaneously within 4–6 weeks. This was demonstrated by Miller and Kane who reported that of stones less than 2 mm, 2–4 mm, and 4–6 mm in size, 95% passed spontaneously by 31, 40, and 39 days, respectively [26]. American Urological Association (AUA) guidelines, based on a meta-analysis of the literature, indicate the median probability of spontaneous stone passage is 68% for stones less than 5 mm (n = 224), and 47% for those greater than 5 mm and less than 10 mm in size (n = 104) [27].

Medical expulsion therapy (MET) has come to the forefront as an additional adjunct to treatment of patients with stones during their observation phase. Pooled analysis suggests that MET with alpha-blockers or calcium channel blockers augments stone expulsion rates, reduces the time to stone expulsion, and lowers analgesia requirements for ureteral stones of less than 10 mm with and without ESWL[28]. In a 2007 meta-analysis of 11 trials that enrolled 911 patients, ureteral stone passage was 44% more likely with alpha-blocker therapy versus conservative treatment [26, 29]. The theory behind the effectiveness of medical treatment is that the calcium channel blockers inhibit endogenous prostaglandin synthesis and calcium influx, reducing spontaneous dysrhythmic contractions of the human ureter. Similarly, alpha-blockers inhibit contractions of ureteral musculature, reduce basal tone, and decrease peristaltic frequency and colic pain, possibly facilitating ureteral stone expulsion [28].

Natural history of calyceal stones

An understanding of the natural history of calyceal stones is imperative to both the prevention and treatment of stones, despite the fact that the natural history of asymptomatic calculi has not been well documented [30]. Hubner and Porpaczy in 1990 assessed the natural history of calyceal stones and found that when left alone, they were likely to continue to increase in size, resulting in further pain and infection. Glowacki *et al.* studied a cohort of 107 patients to establish the natural history of asymptomatic urolithiasis. Seventy-three of 107 patients (68.2%) remained asymptomatic at a mean follow-up of 31.6 months. A symptomatic event

developed in 34 patients (31.8%): spontaneous passage occurred in 16 patients (15%), endoureteral removal was performed in six (5.6%), PCNL in three (2.8%), and nine (8.4%) were referred for ESWL. The cumulative 5-year probability of a symptomatic event was 48.5%. Of the patients who had a symptomatic event, 47% had spontaneous stone passage, while the remainder required intervention [30]. Other investigators have documented similar findings. Moreover, Burgher *et al*. noted that isolated upper pole calculi less than 4 mm in size are significantly less likely to require surgical intervention [23], while mid renal or lower pole calyceal calculi may become symptomatic and thus should be followed with periodic imaging [31]. Additionally, Burgher *et al*. assessed nine patients presenting with pelvic calculi during their study, and these patients had a higher frequency of intervention, stone growth, and observation failure compared with patients with renal calculi in the upper pole that were less than 4 mm. Despite the low sampling size, the conclusion that cannot be overemphasized is that compared to stones located in the upper, middle, or lower pole, pelvic stones should have the most stringent follow-up, as most of these patients (>50%) will require intervention at some point based on growth or symptoms [23].

When stones are seen on repeat imaging, it is difficult to ascertain whether they are newly formed stones or residual stone fragments. Multiple studies have reviewed data regarding stone fragments and their chance of leading to another episode or growth [32–34]. There is no consensus regarding the size of fragment that may be significant after ESWL in terms of later recurrence, stone growth, or subsequent symptoms. Streem *et al*. followed 160 patients with asymptomatic stone fragments of less than 4 mm after ESWL over 26 months: 43% patients had a repeat episode, with 27% requiring intervention. They concluded that the term "clinically insignificant stone fragment" (CIRF), referring to any residual stone after ESWL, is likely a misnomer [35]. One theory is that stone growth may be enhanced after ESWL secondarily to the intervention increasing the surface area of the treated stones [36], potentially leaving a stone nidus that can ultimately result in a symptomatic episode in the future. All attempts should be made to render a patient stone free to avoid the incidence of stone fragments. Stone-free status can be best achieved by selecting the most appropriate treatment alternative for the management of a stone of a particular size, composition, or location.

Staghorn calculi

Despite the discussion regarding the natural history of asymptomatic calculi based on stone location, a particular note should be made about staghorn calculi. These are branched stones that occupy a large portion of the collecting system, and are often referred to as "infection stones" since they are strongly associated with urinary tract infections (UTIs) with urea-splitting organisms. These stones can grow rapidly over a period of weeks to months into a staghorn or branched calculus that involves the entire renal pelvis and, if left untreated, can lead to deterioration of kidney function and endstage renal disease. In a retrospective study of 177 patients with staghorn calculi who were followed over 7 years, renal deterioration occurred in 28% of patients, significantly adding to patient morbidity [37]. Additionally, patients with untreated staghorn stones experienced an increased mortality rate, suggesting that once a staghorn calculus is diagnosed, intervention is warranted. Untreated complex staghorn calculi may result in recurrent UTIs, xanthogranulomatous pyelonephritis, and/or sepsis, and may be better served with a nephrectomy to prevent further patient morbidity, especially when the contralateral kidney is normal [38].

Role of intervention in asymptomatic calculi

Because the natural history of asymptomatic calculi is only poorly understood, judgment regarding the timing and type of pre-emptive intervention must be made without adequate evidence at times, as a period of observation may lead to more invasive procedures in the future for the patient [31]. Despite the prevalence of stone disease in our society, there exists minimal evidence on the optimal intervention with regards to type and timing. Whether prophylactic treatment of asymptomatic stones is justified or not remains to be determined.

Despite the body of literature that exists regarding small calyceal stones, there are many variables that influence the decision to intervene. These variables include parameters such as stone size, possible stone composition, symptoms, and location. Burgher *et al.*'s retrospective study evaluated the natural history of asymptomatic calculi and the risk of progression of disease in 300 male patients with an average age of 62.8 years over a period of approximately 3 years. In their experience, 77% of patients experienced disease progression, with 26% requiring surgical intervention. Disease progression was defined as nonmedical intervention, development of pain during follow-up, and net cumulative stone growth. Those patients with a stone greater than 4 mm on presentation were more likely (26%) to fail observation than patients with smaller solitary calculi. They also found that isolated upper pole calculi of less than 4 mm have lower rates of failure with observation, as none of their patients required intervention over approximately 3 years [23]. Based on their

observations, it would appear that observing stones less than 4 mm in the kidney may be warranted, especially if a stone of this size is located in the upper pole and the patient remains asymptomatic. Asymptomatic stones found in elderly patients and/or those with significant comorbidities may be best managed expectantly, with close observation, utilizing periodic ultrasonography to follow renal calculi for rapid growth or change in location. Certainly, elderly patients with symptomatic stones should be managed similar to a young and otherwise healthy patient with a symptomatic stone.

While most calyceal stones can be treated with ESWL, it is important to be aware of the factors that adversely affect ESWL results. Large stone burden, stones that fragment poorly with ESWL, or stones in particular anatomic positions may be better approached by PCNL or URS. Figure 54.3 demonstrates an algorithm to consider when treating a renal calculus. The most recent AUA guidelines published in 2007 and reviewed in 2009 described the efficacy of intervention strategies for managing ureteral stones based on size of the stone and location within the ureter (Table 54.4). Knowledge of the factors affecting stone clearance will allow the physician and patient to choose the most appropriate treatment approach to achieve maximal stone clearance [31].

Of the trends in distribution of surgical treatment modalities in various databases, ESWL remains the most commonly performed procedure for upper tract stones, followed by URS and PCNL. In analysis, the distribution of procedures in the mid to late 1990s was as follows: ESWL 49–54% of procedures, URS 40–42%, and PCNL 5–6% [1]. Whether achieved by open surgery, PCNL, URS, or ESWL, the common goal remains complete stone clearance, thereby decreasing the risk of stone recurrence and regrowth [31]. At the clinical level, practitioners must consider the concept that urolithiasis is a manifestation of an underlying metabolic or physiologic defect rather than an entity in and of itself, and seek to manage these patients based on this philosophy.

Conclusions

The incidence and prevalence of nephrolithiasis within the USA and throughout the world continues to increase, leading to patient morbidity, need for intervention causing lost productivity, and elevated healthcare costs. The clinical assessment of the stone should be pathophysiology oriented in an attempt to unveil features more proximal to the underlying cause. Dietary and

environmental factors play a major role in the development of renal calculi, and may assist in the prevention of future stones once the etiology is determined. Recommendations for intervention should be made to best benefit the patient with regards to invasiveness, complication, and recurrence.

CHAPTER 55

Initial Choice of Therapy in the Urinary Stone Patient

Peter L. Steinberg[1] **& David M. Hoenig**[2]

[1]Maine Medical Partners Urology, Portland, ME, USA

[2]Albert Einstein College of Medicine/Montefiore Medical Center, Bronx, NY, USA

Introduction

Urolithiasis is a prevalent condition, afflicting 5–10% of the population, at an estimated annual cost of US$2 billion to the American healthcare system [1]. As the front line in managing stone disease, the urologist is armed with numerous tools to manage a patient presenting with a urinary stone. This chapter will focus on adult patients with "normal" renal anatomy, as stones in aberrant urinary systems are discussed elsewhere in Chapters 61–64. Since the focus is elective stone management, patients presenting with sepsis, renal failure, or intractable pain are not discussed, as these situations dictate urgent urinary tract decompression with either ureteral stenting or percutaneous nephrostomy.

The prime modalities discussed are shock-wave lithotripsy (SWL), ureteroscopy/ureterorenoscopy (URS), percutaneous nephrolithotomy (PCNL), medical expulsive therapy (MET), and observation. In recent years, there have been numerous advances in the technology applicable to URS and PCNL, as well as growing evidence of the effectiveness of MET, all of which have altered the approach to the stone patient. Therapeutic decisions in this chapter will be guided by stone location within the urinary system, stone size, stone characteristics and composition, and special factors such as urinary tract anatomy, patient body habitus, and patient comorbidity.

Ureteral stones

The patient with a ureteral calculus can be managed with a variety of modalities, ranging from observation and MET to surgical interventions with URS, SWL, and occasionally PCNL for large proximal stones. Stone size, location, and composition are critical factors in the initial approach to a ureteral calculus. The use of cross-sectional imaging in the diagnosis and management of urinary stone disease is widespread. In recent years, efforts have been made to predict stone composition with computed tomography (CT), and subsequently to guide treatment, especially SWL. Stones with Hounsfield unit measurements over 750–1000 appear to have lower SWL success rates than stones with lower attenuation [2].

Distal ureteral stones

Stones presenting in the distal ureter are amongst those with the highest rate of spontaneous passage [3]. Once they have traversed the proximal and mid ureter, the ureterovesical junction (UVJ) remains a common site for stones to become impacted and obstructive (Figure 55.1A). The size of the calculus is critical to the assessment of potential for spontaneous passage versus the decision to intervene. Generally speaking, smaller stones that are further along the ureter have a greater chance of spontaneous passage than larger stones in a more proximal location. Pooled data presented in the American Urological Association (AUA) ureteral calculus guidelines from 2007 suggest a 68% rate of stone passage for ureteral calculi under 5 mm in size(based upon 224 patients from five studies), and for stones of 5–10 mm in size there is a 47% rate of passage (based

Smith's Textbook of Endourology, Third Edition. Edited by Arthur D. Smith, Gopal H. Badlani, Glenn M. Preminger, Louis R. Kavoussi.

upon 104 patients from three studies) [3]. Supportive data exist from an observational study of 75 patients with ureteral calculi observed for spontaneous passage [4]. Amongst this cohort, stones greater than 4 mm in size required intervention 50% of the time [4]. Stones smaller than 2 mm in size passed on average at 8 days; stones of 2–4 mm passed on average at 12 days; and stones greater than 4 mm passed on average at 22 days. Of stones that did not require intervention, 95% passed within 30–40 days [4].

A trial of MET is warranted in nearly all patients with uncomplicated presentation of distal stones of 1 cm or smaller. Two meta-analyses have examined the role of both alpha-antagonists and calcium channel blockers (CCBs) to increase the rate of stone passage, as well as to hasten stone passage, and most of the existing data are for stones averaging over 5 mm in size [5, 6]. Both studies support an increased rate of stone expulsion with alpha-blockers and CCBs. The review from Hollingsworth *et al*. suggests a 65% increased rate of stone expulsion with either agent, and the number needed to treat (NNT) to lead to one additional stone expulsion was 4 [5]. A study from the emergency medicine literature, pooling data from 16 alpha-blocker studies and nine CCB studies, shows a 59% greater rate of passage with alpha-blockers and a 50% greater rate of passage with CCBs [6]. The NNT with alpha-blockers was 3.3 and for CCBs 3.9 [6]. The complication rate for alpha-blockers was 4% and for CCBs 15%. Based upon their own analysis of the data, the AUA suggests alpha-blockers are the preferred agent for MET [3]. Although most studies with alpha-blockers investigated tamsulosin, equivalent efficacy has been seen with terazosin and doxazosin as well [7].

If a trial of MET fails, there are data to suggest an additional trial of MET is warranted in select patients, with a subsequent increase in the rate of spontaneous stone passage [8]. If this is ultimately unsuccessful, then surgical therapies become appropriate. In the distal ureter, both SWL and URS are highly efficacious.

Pooled data from thousands of patients in the most recent AUA ureteral stone guidelines provide a robust source of outcomes data for both URS and SWL on distal ureteral stones (Figure 55.1B). Based upon nearly 7000 patients who underwent SWL and 6000 who underwent URS, the overall success rate for SWL is 74% in the distal ureter and 94% in the proximal ureter . Distal stones of 1 cm or smaller had an 86% clearance rate with SWL and 97% with URS, and those greater than 1 cm were cleared at rates of 74% and 93%, respectively [3]. Overall, these rates are very close, and clearly both modalities afford an excellent opportunity for stone eradication in the distal ureter. Based upon this analysis, the average patient undergoing SWL for a distal ureteral stone requires 0.37 adjunctive procedures for stone clearance [3].

A Cochrane Review was performed of the small number of randomized trials comparing URS and SWL for ureteral stones. These studies were not limited to distal stones, though four of the five studies included were based on distal stones alone. This review reported a slightly higher success rate for URS, a slightly higher

rate of adjunctive procedures needed with SWL, and a slightly lower rate of complications with SWL [9].

Given these factors, how is the initial choice of surgical management in distal ureteral stones best approached? Patient preference and comorbidity, and surgeon preferences must be taken into account in order to decide on the optimal treatment plan. From an anesthetic standpoint, URS can generally be performed under either spinal or general anesthesia, while SWL can usually be performed with sedation. Availability of appropriate equipment may be a factor, as not all centers have ready access to various technologies "on demand," potentially leading to unacceptable delays with one modality. Finally, there remains some concern in women of childbearing age that SWL may be harmful for fertility, and thus it is not suggested for use in the distal ureter in this patient population [10].

Common side effects of SWL include incomplete stone fragmentation or passage, necessitating additional procedures. Patients with a propensity to hemorrhage or on anticoagulants are not candidates for SWL unless these can be stopped. URS entails its own set of risks, including injury to the ureter, such as perforation or stricture, and proximal migration of stone fragments, though serious complications do occur in less than 5% of patients in modern series [11]. In addition, although not all urologists use stents after routine URS, many do and these can contribute to substantial postoperative morbidity.

Given this information, it seems apparent that a trial of MET is appropriate in virtually all patients with uncomplicated distal ureteral stones. If MET fails, surgical therapy may be required, and URS affords a slightly higher success rate than SWL, though it is associated with a higher rate of complications. Overall, the choice of URS or SWL for a distal ureteral stone lies with the available expertise and equipment, and with the patient after an informed discussion of the risks and benefits of each modality. Armed with the knowledge that both modalities lead to high rates of stone clearance, additional factors such as the potential need for stenting, type of anesthetic used, and complication profile of each procedure can be used to guide the choice of therapy.

Proximal and mid-ureteral stones

Optimal management of these stones depends heavily upon the size of the calculus in question. As described above, larger and more proximal stones are associated with a lower rate and longer time to spontaneous passage than smaller and more distal stones [3, 4]. Management of mid- and proximal ureteral stones is slightly different from that of distal stones, with the largest difference being the lack of evidence for MET in mid- and proximal ureteral stones, as this has not been specifically tested. Operative intervention consists primarily of either SWL or URS, though there is a select role for antegrade approaches to large proximal calculi.

Nonetheless, observation may be a reasonable first-line approach in patients with a small mid- or proximal ureteral stone. If the calculus migrates distally, then MET obviously becomes a treatment choice. Assuming the stone does not appropriately progress, or the patient is otherwise unable to tolerate continued observation, then surgical therapy is appropriate.

Once again, pooled data from multiple studies are provided by the recent AUA guidelines delineating outcomes in the management of proximal and mid-ureteral stones. For stones in the mid ureter, pooled data on 1600 SWL patients and 1000 URS patients is available; SWL had a 73% success rate and URS an 86% success rate [3]. When stratified by size, there is essentially equal stone clearance for stones greater than 1 cm in size, with rates in the 76–78% range. Stones of 1 cm or smaller have an 84% clearance with SWL and 91% with URS [3]. The rate of secondary procedures is slightly higher when SWL is used to manage mid-ureteral stones than when URS is, especially for stones of greater than 1 cm in size. Nearly 1.3 procedures per patient are needed when SWL is used as a first line treatment option with mid-ureteral stones of 1 cm or smaller, and 1.76 procedures per patient are needed for clearance with stones of greater than 1 cm in size [3]. When URS is utilized, 1.04 procedures per patient are needed to achieve stone clearance [3].

Some general issues with the management of mid-ureteral stones with SWL arise, because the structures of the bony pelvis can interfere with visualization and treatment of the stone (Figure 55.2). In some lithotriptors, a prone position must be used to assure the stone is in the ideal position for treatment.

Regarding URS for the mid-ureteral stone, traversing the iliac vessels may sometimes present significant challenges, though the use of flexible scopes and instruments usually minimizes this issue. Proximal stone migration is possible, though usually does not present significant difficulties if the surgeon is proficient with flexible URS.

As with distal stones, a similar decision-making process is undertaken for mid-ureteral stones. The relatively less invasive nature of SWL, somewhat lower rate of success in the mid ureter, and the possibility it can be performed with sedation with lower risk, must be weighed against the greater efficacy and invasiveness of URS.

For proximal ureteral stones of greater than 1 cm in size, or for stones of 1 cm or less that have failed a period of observation, the urologist must decide between URS, SWL, and antegrade approaches to the stone, balancing optimal stone clearance against morbidity.

Figure 55.2 CT of right mid-ureteral stone (demarcated by lines). Note the presence of the sacrum and iliac bones posterior, which can interfere with shock transmission.

Overall, success rates for single procedures in the proximal ureter are slightly lower than in more distal locations. Based upon the pooled data in the most recent AUA guidelines, both SWL and URS are associated with roughly 80% success rates [3]. When calculi are 1 cm or smaller in size, SWL has a slight advantage over URS in terms of stone clearance (90% vs 80%); however, when stones are more than 1 cm in size, SWL is associated with a clearance rate of 68% and URS of 79% [3]. Furthermore, once stones over 1 cm are treated, there is a greater need for adjunctive procedures with SWL. For proximal ureteral stones of over 1 cm in size, the average patient requires 1.5 procedures for clearance with SWL as opposed to 1.07 with URS [3].

A recent meta-analysis of SWL versus URS for proximal calculi came to similar conclusions as the AUA guideline panel. The study confirmed that both modalities are effective, with essentially equivalent outcomes for stones of 1 cm or smaller in size [12]. For stone sizes over 1 cm in size, a preference for URS was noted, given its 6% higher stone-free rate [12]. Complications were minimal in the SWL patient; the ureteral stricture rate was roughly 2% in this review [12].

An additional consideration to aid in selecting optimal initial therapy for proximal ureteral stones focuses on the costs incurred with treatment. A cost analysis from Lotan *et al*. shows that URS is less costly than SWL for proximal stones when performed primarily [13]. When considering the higher rate of adjunctive procedures for SWL compared with URS, the cost differential is even greater and is something to potentially consider when deciding how to approach the patient with such a stone [13].

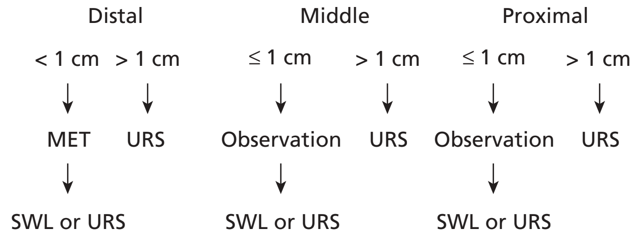

Figure 55.3 Ureteral calculi: optimal initial management strategy. MET, medical expulsive therapy; SWL, shock-wave lithotripsy; URS, ureterorenoscopy.

In select cases of very large stones in the proximal ureter, or stones which are heavily impacted and do not permit retrograde access, a patient can be offered an antegrade procedure for clearance [14]. Both rigid and flexible nephroscopy can be used to approach the UPJ and proximal ureter, with appropriate instrumentation to allow a high success rate. In addition, following treatment of the stone, fragments can be removed via the percutaneous tract, obviating the need for passage. The percutaneous approach is used much less frequently than either URS or SWL for these stones, so specific data to support the practice or describe complications approaching proximal ureteral stones are minimal. Nonetheless, given the extensive experience with PCNL for renal calculi, this approach is a viable option for the select patient with a proximal ureteral stone.

Summary

The patient with an uncomplicated ureteral stone is best managed initially with either MET for distal stones, or a period of observation for mid- and proximal ureteral stones (with MET if the stones progress down the ureter). If surgical therapy is indicated, URS generally leads to higher stone-free rates than SWL, though is associated with a higher rate of complications and is more invasive. A frank and informed discussion about the risks and benefits of each surgical approach, individual patient factors, and consideration of stone composition, size, and location, are the optimal means of choosing the most appropriate surgical stone therapy (Figure 55.3).

Renal stones

As in the ureter, both stone size and location are critical to the choice of optimal initial therapy in the renal stone patient. Unlike the ureter, where anatomy is generally straightforward and of little consequence for surgical

planning, intrarenal anatomy and patient body habitus can play significant roles in deciding which treatment options are best for each patient. Additionally, stone composition is vitally important, as it heavily impacts the outcomes of SWL, in particular.

For renal stones of 1 cm or smaller that are asymptomatic, nonobstructing, and not associated with infection, a reasonable strategy is one of observation. Periodic assessment of the patient for symptoms and the stone for growth with a plan for deferred management is reasonable. Following the stone with kidney, ureter, and-bladder radiography (KUB) and ultrasound at semiannual or annual intervals is a sensible approach: stone progression or the development of obstruction can be readily detected, and compared to CT limits radiation exposure for the patient. In addition, pursuing metabolic evaluation in these patients is prudent and advocated by several authors, in an effort to limit the growth of calculi while under observation [15, 16].

The rate at which these stones become symptomatic is hard to precisely define, as there is only a small body of literature reporting on a paucity of patients with renal stones undergoing observation only. For all patients, the chances of symptoms referable to a renal calculus range from 31% at 2.5 years [17], to roughly 50% at 5 years [16], and to nearly 70% at 7 years [18]. A contemporary cohort of 300 patients, with an average stone size of 1.1 cm, showed a 77% rate of progression (symptoms, need for surgery, or stone growth) over 3 years [19]. Among these patients, 26% needed surgery over that time period [19]. Larger stone burden and more stone episodes were risk factors for symptoms and the need for intervention [17, 19]. One randomized trial of patients with asymptomatic calyceal stones smaller than 1.5 cm in size showed no advantage of performing elective SWL versus a period of observation [20]. The NNT in this trial was 10, and the authors concluded that observation was an appropriate strategy with asymptomatic calyceal stones of less than 1.5 cm in size [20].

Armed with the knowledge that a renal stone has a moderate chance of ultimately causing symptoms and requiring operative intervention, individual treatment plans can be tailored to each patient based on their clinical presentation.

Renal stones 1 cm or smaller in size

Assuming active treatment is sought, there are three options for managing a renal stone up to 1 cm in size: SWL, URS, and PCNL. Initially we will consider stones located outside of the lower pole (Figure 55.4). SWL is still a first-line option for these stones, especially for a stone of low attenuation on CT scan, in an interpolar, upper polar, or renal pelvic location, and in a calyx with a normal infundibulum [15]. Even if the stone is not

Figure 55.4 CT scan of left renal pelvic stone (demarcated by lines).

radio-opaque, ultrasound can be used to help localize a calculus for SWL in the kidney.

Highest clearance is achievable with stones in the renal pelvis, with reported success rates of 80–90% [15]. In upper and interpolar locations, clearance rate is closer to 70% [15]. Although CT does not perfectly predict the composition of stones, stones with higher Hounsfield units (over 750–1000) are less susceptible to management with SWL, and this is a reasonable means of stratifying treatment [3, 21, 22]. Additionally, body habitus in terms of the skin–stone distance is a critical factor in appropriate patient choice for SWL, with a skin–stone distance of over 10 cm associated with poorer outcome for that procedure [21, 22].

URS is a reasonable choice for many renal stones, as modern ureteroscopes can reach the entire collecting system and displace a stone to a readily accessible location for lithotripsy or basket removal. This achieves equivalent outcomes to SWL for calculi located within the kidney across all stone compositions, with very low morbidity [15]. Stone-free rates of approximately 80% can be expected for renal stones of 1 cm or smaller in size treated by URS [15]. In the patient with a high attenuation stone or a large skin–stone distance, URS is preferred to SWL as the difference in success rate is significant [15].

Finally, PCNL yields very high clearance rates for small renal calculi, but is a relatively morbid procedure for a stone of 1 cm or less, considering the success rates achieved with less invasive procedures [15]. In general, PCNL should not be considered as optimal initial man-

agement in renal stones of 1 cm or less, unless extraneous factors are at play.

For stones of 1 cm or less in the lower pole, the decision-making is slightly more complex. Assuming observation has failed or surgery is required for symptomatic stones, again the urologist is faced with a choice between SWL, URS, and PCNL. As with stones in the remainder of the kidney, a low attenuation stone and a favorable skin–stone distance would favor SWL, while the converse would favor URS. In this patient population there is just one small randomized trial to guide decision-making [23]. A total of 67 patients were randomized to either URS or SWL for 1-cm or smaller lower pole stones. Although stone-free rates were uniformly low (35% for SWL and 50% for URS), it should be noted that follow-up was performed with CT, which is extremely sensitive for detecting fragments [23]. There was no statistically significant difference between the two techniques, but URS did lead to a slightly higher stone-free rate and was associated with more complications [23]. Percutaneous management remains an excellent option for stone clearance, but, once again, the trade-off in morbidity and invasiveness for that optimal success rate must be considered. Unfavorable renal anatomy, such as a long infundibulum or acute angle of the lower pole calyx, or extremely dense/difficult to fragment stones may make PCNL the optimal initial choice.

Renal stones 1–2 cm in size

As renal stones increase in size, management changes slightly; PCNL assumes a more important role, as its superior ability to clear stones is a reasonable trade-off for the higher morbidity of the procedure. In addition, especially in the lower pole, SWL becomes a less effective modality. URS is useful for many of these stones, though its role is not as well tested as SWL or PCNL.

For renal stones, SWL remains a treatment option in this size range. A nomogram developed by Kanao *et al*. offers good estimates of stone clearance and can help guide decision-making [24]. For a renal pelvic stone, the chances of clearance at 3 months after a single SWL session are 43% for stones of 16–20 mm and 64% for stones of 11–15 mm in size [24]. For stones located in a calyx, the comparable stone-free rates are 35% and 57%, respectively [24].

As already stated, advances in equipment for stone management over recent years mean that virtually any location in the kidney can be readily accessed with flexible ureteroscopes. Concomitantly, there has been an effort to manage larger renal calculi with URS in order to assess its role compared with the more invasive PCNL (Figure 55.5). A small study of URS compared to PCNL for 1–2-cm renal stones showed a slightly lower stone-free rate of 67% versus 87%, but without any complications in the URS arm [25].

With this size of stone, especially in the lower pole, PCNL assumes the more dominant role in management. The morbidity of the procedure is often tolerable given the uniformly high clearance rates after PCNL compared with alternatives. In the Lower Pole I study, PCNL led to 93% stone-free rates in 1–2-cm lower pole renal stones, versus 23% for SWL [26]. In the URS versus PCNL trial mentioned above, there was a 20% higher rate of stone clearance with PCNL [25]. Auxiliary procedures were required in close to 40% of cases after SWL, as compared to a mere 6% with PCNL for 1–2-cm lower pole stones [26].

Renal stones greater than 2 cm in size

When approaching stones greater than 2 cm in size, the success rate of PCNL is unparalleled compared with the alternatives. Both SWL and URS have been utilized with stones of this size, but clearance often requires multiple procedures, whereas PCNL still has a high rate of success with one procedure.

The nomogram by Kanao *et al*. suggests clearance for renal stones greater than 2 cm in size is 30% for renal pelvic stones and 23% for calyceal stones [24]. Likewise, for URS stone clearance is feasible for stones over 2 cm in size, but this requires an average of 2.3 URS procedures per patient [27]. In the Lower Pole I cohort, six of seven patients with stones greater than 2 cm in the lower pole were cleared with PCNL, whereas only one in seven patients were cleared with SWL (Figure 55.6) [26].

Clearly, for staghorn calculi and assuming that adequate renal function is present, PCNL is the mainstay of treatment, with procedures such as laparoscopic and open pyelolithotomy/nephrolithotomy being reserved for unique situations. (Figure 55.7) Stone-free rates approach nearly 80% with a single percutaneous procedure [28], and can reach up to 95% when flexible scopes and laser lithotripsy are included in the procedure [28].

In one study involving patients with renal large stones in whom PCNL was contraindicated or refused, a combination therapy using SWL + URS has been described [29]. The authors reported a low initial procedure success of 14%, but when combined with medical therapy or second-stage SWL and/or URS, a stone-free rate of nearly 77% was achieved [29].

Summary

For renal stones, several variables contribute to the decision as to which stone therapy is optimal for initial management. For asymptomatic stones of 1 cm or smaller in size, a trial of observation is certainly reasonable, though patients should be aware that stones

often require treatment or become symptomatic with the passage of time. For stones of 1 cm or smaller in size that warrant treatment, SWL and URS are associated with fair-to-moderate clearance rates and relatively low morbidity. As stones increase in size, especially with a lower pole location, PCNL becomes the most important means of treatment. As stones increase in size over 2 cm, PCNL is the preferred means of management (Figure 55.8).

Stones in calyceal diverticula

Stones presenting in a calyceal diverticulum are an infrequent occurrence, though often symptomatic. Treatment options available for these calculi include SWL, URS, PCNL, and laparoscopic approaches [30]. Since this condition is relatively rare, robust data comparing treatment modalities are lacking.

In a 15-year retrospective assessment comparing SWL and PCNL, PCNL had a much greater stone-free rate of 83%, while for SWL it was only 21% [31]. On the other hand, 61% of patients treated with SWL were rendered symptom free. Recurrence rates were roughly 10% in each group [31].

URS is also efficacious, especially when the diverticulum has a narrow and stenotic neck, hindering passage of fragments after SWL [32]. Using both the flexible ureteroscope and the holmium laser, many of these diverticula can be cleared of their stone burden, with smaller stones again being more amenable to successful clearance.

In the case of a posterior diverticulum, PCNL is an excellent means of accessing the diverticulum, as well as clearing its stone burden and possibly ablating the lining of the diverticulum [30, 32]. Finally, in the event of an anterior diverticulum, a laparoscopic approach has been successfully applied and thus offers an additional treatment option [30].

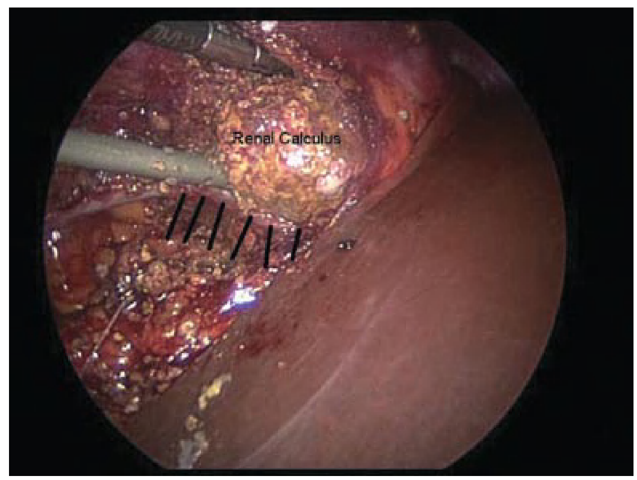

Figure 55.9 Intraoperative view during laparoscopic pyelolithotomy. The stone is visible as it is being extracted, while the lines demarcate the edge of the pyelotomy incision.

Laparoscopic and open stone surgery

The advent of SWL, better ureteroscopes, and PCNL has essentially rendered conventional stone surgery obsolete. Nonetheless, circumstances do arise, though rarely, where a laparoscopic or open approach is indicated [33]. For ureteral calculi, operative intervention is rarely needed; however, large impacted stones that fail SWL, URS, or antegrade removal would be candidates [33]. For such stones a laparoscopic approach can be utilized *in lieu* of an open ureterolithotomy [33].

For renal stones, an open or laparoscopic approach can be considered in select circumstances as well (Figure 55.9). In the event of failed PCNL, SWL, or URS,

especially after multiple procedures, there is a role for formal operative intervention [33]. Additionally, in the event of a staghorn calculus where clearance seems unlikely in a reasonable number of minimally invasive procedures, open or laparoscopic surgery is an option [33]. Occasionally concomitant surgery on an unrelated organ system would be an indication to perform an open procedure on a large renal stone, as would concurrent surgery to repair a ureteral stricture [33]. Finally, some patients' body habitus precludes fluoroscopy, endoscopy, or positioning for SWL and thus leaves the surgeon with no choice but an open or laparoscopic approach to a urinary stone [33].

Conclusions

Modern stone management involves multiple treatment choices for the urologist. Salient features of contemporary management include the increasing role for MET in distal ureteral stones, the increasing role of URS for ureteral stones of all locations, especially those of higher density unlikely to respond to SWL, and the unparalleled role of PCNL for renal stones greater than 2 cm in size.

CHAPTER 56

Management of Urolithiasis during Pregnancy

Petar Erdeljan & John D. Denstedt

Division of Urology, Department of Surgery, Schulich School of Medicine & Dentistry, The University of Western Ontario, London, Ontario, Canada

Anatomic changes during pregnancy

Pregnancy induces a number of anatomic changes within the urinary tract. Renal size increases secondary to an increase in renal vascular volume and increase in the renal interstitial space. Hydronephrosis of varying severity is experienced by approximately 90% of pregnant women by the third trimester. The hydroureter extends to the sacral promontory and is typically absent more distally. The hydroureteronephrosis of pregnancy results primarily from compression of the gravid uterus [1]. Physiologic hydronephrosis can affect 90% of right kidneys and up to 67% of left kidneys [2]. The hydroureter is more prevalent and severe on the right side, secondary to uterine dextrorotation as well as a pressure-reducing effect of the sigmoid colon on the left side. The ureteric smooth muscle relaxation due to increased levels of progesterone has also been implicated in the development of gestational hydronephrosis [3, 4]. However, this mechanism may contribute to the early development of hydronephrosis, between 6 and 10 weeks of gestation, while the mechanical factor remains the major cause thereafter. Support for a primarily mechanical theory includes absence of urinary tract gestational ureteral dilation below the pelvic brim in patients with a pelvic kidney and in those who have undergone previous urinary diversion. The bladder is displaced anterosuperiorly by the gravid uterus, bladder capacity increases, and the detrusor muscle becomes relatively hypotonic and has decreased sensation (Table 56.1). The urothelium becomes congested and hyperemic.

Physiologic changes during pregnancy

Pregnancy induces physiologic changes in many organ systems, including the renal system (Table 56.2). Glomerular filtration rate (GFR) and renal plasma flow (RPF) increase by 40–65% and 50–85%, respectively [5] secondary to an increase in the cardiac output and decrease in the renal vascular resistance. Creatinine clearance increases by up to 50% [6], leading to lower serum creatinine and urea levels, a higher level of filtered glucose and glucosuria, and higher level of urine sodium, calcium, uric acid, citrate, magnesium, and glucosminoglycans. Enhanced renal filtration additionally affects dosing of antibiotics as well as anesthetic agents. Other nonrenal systems undergo physiologic changes as well.

Mineral metabolism and stone formation during pregnancy

The homeostasis of urolithiasis-promoting and -inhibiting factors is altered in pregnancy.

Placental 1,25-dihydroxycholecalciferol increases intestinal resorption of calcium as well uptake of calcium from bone. The increase in absorbed calcium is offset by an increase in GFR and subsequent increased filtered load of calcium. Parathyroid hormone (PTH) secretion is decreased, suppressing the tubular resorption of calcium. Thus, serum calcium levels generally remain unchanged and hypercalciuria occurs. Uric acid and oxalate excretion is increased due to increased GRF, and

Gastrointestinal	↓ Gastrointestinal motility
	Relaxation of gastroesophageal sphincter

fetal and dietary factors [6–8]. Hypercalciuria, uricosuria, and oxaluria all create a favorable environment for renal calculus formation.

Pregnancy, however, is not associated with an increased incidence of urolithiasis compared to the nonpregnant population [9, 10]. This is most likely explained by the increase in filtered citrate, magnesium, and glycosaminoglycans [6–8], all of which are known inhibitors of crystal aggregation and growth.

Table 56.3 Differential diagnosis of acute abdominal pain in pregnancy.

Urologic causes	Gynecologic and obstetric causes	General surgical causes
Urolithiasis	Premature labor	Appendicitis
Pyelonephritis	Placental abruption	Cholecystitis
	Chorioamnionitis	Diverticulitis
	Ectopic pregnancy	Intestinal obstruction
	Ovarian torsion	Gastroenteritis
	Pelvic inflammatory disease	Hernia
		Pancreatitis
		Mesenteric lymphadenitis

Renal calculi during pregnancy are documented to be composed primarily of calcium phosphate (74%) and calcium oxalate (26%) [11].

Incidence

The incidence of symptomatic urolithiasis in pregnancy is between 1 in 244 and 1 in 2000 pregnancies [12–14]. The overall incidence of urolithiasis is uncertain, but is estimated to be higher, as some asymptomatic renal calculi may remain undetected. There are no observed differences in the rate of urolithiasis between pregnant and nonpregnant women [15, 16].

The average age of presentation is 27 [17] with 80–90% of cases detected during the second and third trimester. Urolithiasis seems to be higher in multiparous women, in caucasian patients, and in patients with a history of hypertension and renal disease [17, 18]. Ureteral calculi present twice as often as renal calculi [19, 20]. Up to 30% of patients have a history of stone disease [21].

Presentation

Symptomatic pregnant patients may present with abdominal or flank pain (85–100%), gross (15–30%) or microscopic hematuria (95–100%), lower urinary tract symptoms, urinary tract infection, pre-eclampsia, and premature labor [22–24]. Nausea and vomiting are invariably present as well. A comprehensive differential diagnosis of abdominal pain during pregnancy is given in Table 56.3.

Acute abdominal or flank pain in pregnancy presents a unique diagnostic challenge. The clinician has to consider anatomic alterations induced by pregnancy that can lead to various conditions mimicking each other. For example, the appendix can be displaced superiorly after the first trimester and appendicitis may mimic pyelonephritis or cholecystitis [25].

Table 56.4 Fetal radiation doses for radiologic tests.

Procedure	Fetal dose (mGy)
CT scan (conventional)	8.0–49
CT scan (limited)	0.244–1.372
IVU	1.7–10
KUB	1.4–4.2
Nuclear renogram (MAG3 or DTPA)	0.2–4.0
MRI	No radiation, no known adverse effects
Ultrasonography	No radiation, no known adverse effects

CT, computed tomography; IVU, intravenous urography; KUB, kidneys, ureters, bladder plain film; MAG3, mercaptoacethyltriglycine; DTPA, diethyltriamine pentaacetic acid; MRI, magnetic resonance imaging.

Diagnostic tests

Imaging and radiation exposure

Accurate diagnosis of abdominal pain in pregnancy largely depends on diagnostic imaging. The necessity of diagnostic imaging and exposure to ionizing radiation is commonly anxiety provoking for both patients and clinicians. Use of the ionizing radiation needs to be avoided whenever possible, due to its potential teratogenic effects. When its use is unavoidable, a detailed discussion with patients is required, carefully explaining the potential risks associated with its use. Application of radiation dose reduction techniques is mandatory. The delivered dose of radiation should be as low as possible, while maintaining the quality of diagnostic image that is useful for diagnosis. Effects of ionizing radiation on the fetus can be categorized into four classes: intrauterine fetal death, fetal malformation, disturbance of growth and development, and mutagenic–carcinogenic effect [26, 27]. The risk of exposure is also dependent on the dose of the radiation and fetal gestational age [28].

The radiation dose is measured in Gray units (Gy, SI system), representing the amount of ionizing radiation absorbed by tissue. Previously, the radiation dose was measured in rads (1 Gy equating to 100 rads), representing the radiation dose delivered and not necessarily absorbed by the tissues. The delivered fetal dose for each diagnostic imaging procedure varies according to the technique used (Table 56.4) and maternal body configuration. Most diagnostic procedures deliver fetal doses below 50 mGy [29]. This dose of radiation has not been associated with an increase in fetal anomalies or pregnancy loss [30]. The American College of Obstetricians and Gynecologists recommends that "Women should be counseled that the X-ray exposure from a single diagnostic procedure does not result in harmful effects" [30].

Table 56.5 Effects of significant radiation exposure on the fetus.

Gestational age (weeks)	Radiation effect
2–4	All lethal or no impact on fetus, without any malformations present
4–10 (organogenesis)	Microcephaly, growth retardation, gross malformations
10–17 (peak neurologic development)	Microcephaly, mental retardation, growth retardation and sterility in adult life
17–40	Adverse effects seen rarely, if ever

The effects of radiation depend on the fetal gestational age [28]. Fetal tissues are most susceptible to ionizing radiation during the first trimester when organogenesis is occurring. Use of ionizing radiation should be avoided during this period. The teratogenic effects of radiation are summarized in Table 56.5. In addition, ionizing radiation has a potential to induce development of childhood cancers such as leukemia. Historic studies raised concern that *in utero* radiation exposure may increase the incidence of childhood malignancy by 1.3–2 times [28, 31]. However, more recent investigations have reputed this evidence [32]. The National Radiological Radiation Board concluded that the majority of diagnostic radiologic procedures performed in an individual pregnancy presents no substantial risk and carries a less than 1 in 5000 chance of developing a fatal childhood cancer (1 in 33 000 per mGy). Additionally, the risk is less than 1 in 10 000 for development of induced inheritable disease (1 in 40 000 per mGy) [33, 34].

Ultrasound

Ultrasonography (Figure 56.1) is the most useful initial test when acute abdominal or flank pain in pregnancy is investigated. The appeal of ultrasound derives from the lack of ionizing radiation and absence of harmful effects, documented over many years of use. Ultrasonography can effectively evaluate the renal parenchyma, pelvicalyceal system, dilated ureter, and to some extent visualize renal and ureteral calculi.

The accuracy of ultrasonography in the detection of renal calculi is reported to be between 34% and 86% [17–19]. This wide variation in the reported accuracy most likely derives from the fact that ultrasound is operator dependent. Additionally, ultrasonography is very nonspecific and often cannot distinguish between

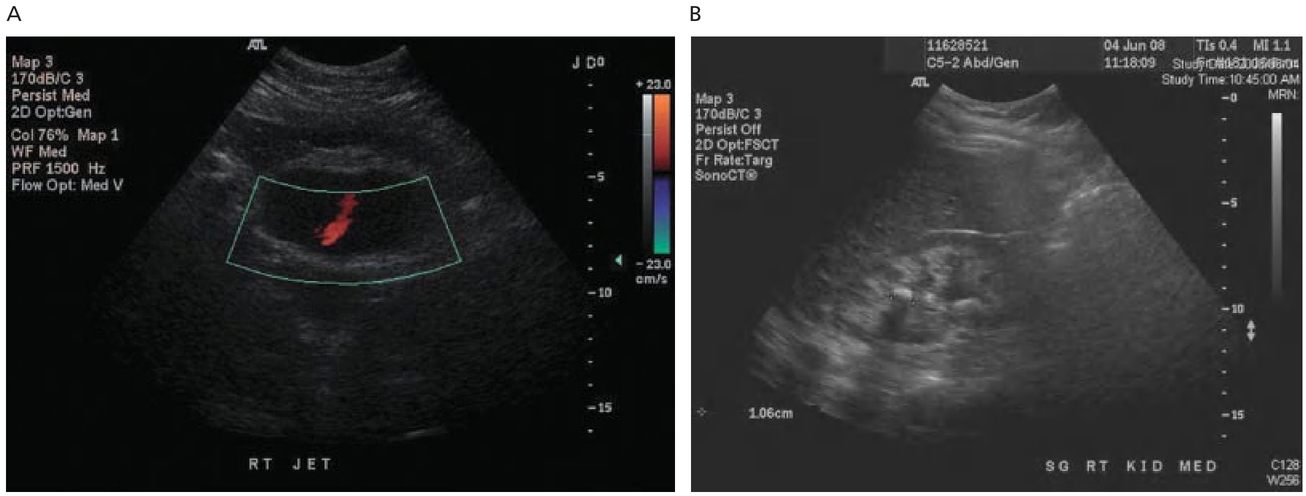

Figure 56.1 Ultrasound images. (A) Bladder (Doppler) demonstrating an absence of left ureteric jet, in a 30-year-old pregnant woman, G1P1 GA 30 weeks. (B) Kidney with a right renal stone in a 31-year-old pregnant woman, G2P2 GA 28 weeks.

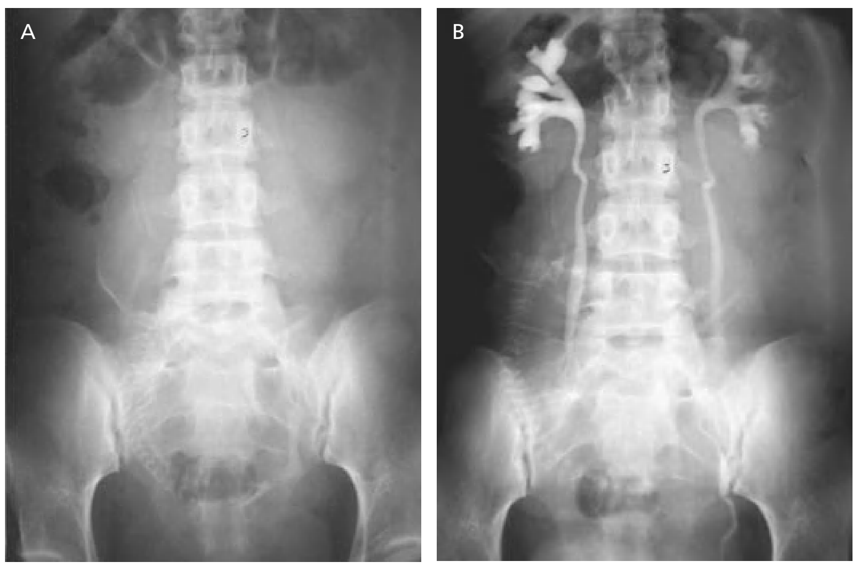

Figure 56.2 (A, B) Kidneys, ureters, and bladder intravenous urogram demonstrating a right ureteral calculus in a 30-year-old pregnant woman, G1P0 GA 29 weeks.

hydronephrosis of pregnancy and that secondary to calculi.

Several modifications to ultrasonography have attempted to improve its accuracy. Transvaginal ultrasound was demonstrated to be effective in the detection of distal ureteral calculi [35]. Detection of hydroureter below the pelvic brim, with any ultrasound approach, may alert the operator to the presence of distal ureteral calculi [36]. The presence of ureteral jets on ultrasound or Doppler ultrasound can exclude complete ureteral obstruction in 80–100% of cases [37].

Resistive index (RI) measurements may increase the accuracy of ultrasonogarphy in distinguishing between the physiologic dilation and calculi-related obstruction [38]. An RI of 0.70 was demonstrated to have 87% accuracy, 45% sensitivity, and 91% specificity for diagnosis [38, 39]. Additionally, a difference in RIs (ΔRI) between the affected side and the normal contralateral kidney of 0.06 increases the sensitivity of ultrasonography to 95%, with specificity of 100% and accuracy of 100% [39]. This type of ultrasonography adjunct was demonstrated to be limited by pre-existing renal disease, nonsteroidal anti-inflammatory drugs (NSAIDs) and acute onset of obstruction (<6 h).

Intravenous urography

Intravenous urography (IVU) (Figure 56.2) is effective in describing anatomy and function of the collecting system, along with the site and degree of potential

obstruction. IVU can be considered as a second-line investigation for hydronephrosis of pregnancy. Small published series report relatively high specificity in diagnosing renal calculi in pregnancy [17, 40]. If needed, a limited three-shot protocol should be used: a scout film, 15–20-min film, and a selected delayed image at 2 h. Fetal shielding should be used at all times [41].

IVU, if considered, should be used judiciously due to potential risks of intravenous contrast and fetal radiation exposure. Intravenous contrast was demonstrated to cross the placenta in small quantities, but without any described teratogenic effects [42]. However, exposure to iodinated intravenous contrast during late pregnancy can lead to fetal thyroid suppression, and requires screening for neonatal hypothyroidism [42].

A limited IVU delivers 0.5 mGy of radiation to the fetus, which is below the 5 mGy safety point. Fetal shielding and films obtained in a prone position can further reduce the dose.

Computed tomography

A traditional computed tomography (CT) scan (Figure 56.3) remains contraindicated in pregnancy due to the high dose of ionizing radiation delivered. Recently, however, a low-dose CT scan protocol has been described for the detection of renal calculi during pregnancy. A low-dose CT scan protocol uses a pitch of 1.5 (from 0.75 in regular CT), 120 kV, and a mean of 109 mAs. With these modifications the mean delivered fetal radiation exposure is 705.5 mrad (range 244–1372), although this is probably an overestimate due to maternal changes in body geometry. Obese patients receive a higher estimated dose on average. The resulting CT images are of much lower quality in comparison to traditional scans, but this investigation still provides high sensitivity and specificity for detection of renal and ureteral calculi.

Figure 56.3 Low-dose CT scan demonstrating a right ureteral calculus in a 29-year-old woman, G1P0 GA 27 weeks (reproduced by permission of Mary Ann Liebert).

Based on the finding of a small Research Ethics Board (REB)-approved study, the authors concluded that a low-dose CT scan is more sensitive than ultrasound and improves decision-making. The judicious use of low-dose CT scans in pregnant women with flank pain and negative initial ultrasound is advocated [43].

Magnetic resonance

Magnetic resonance imaging (MRI) (Figure 56.4) in pregnancy produces high-quality images of urinary tract anatomy. Heavily weighted T2 MRI pulse sequences or use of intravenous gadolinium can produce precise urograms, comparable to those produced by IVU. The accuracy of MRI in delineating pathologic obstruction from hydronephrosis of pregnancy ranges from 93% to 100% [44]. MRI's diagnostic accuracy can be enhanced by combining it with Doppler ultrasonography and nuclear renography [45]. To date, no harmful effects have been reported with the use of MRI in pregnancy [46]. Experience with gadolinium is limited, but to date no adverse effects on a fetus have been reported. The National Radiological Radiation Board recommends avoiding gadolinium in the first trimester of pregnancy. The main limitation of MRI remains the inability to visualize the stone. The presence of the stone has to be inferred from several soft signs such as "signal voids," "double kink," and perinephric and periureteral edema. Additional limitations include the time-consuming nature of performing MRI (although this continues to improve with new generation scans), its lower availability, and high costs. Patients afflicted with claustrophobia also will not be able to undergo this diagnostic procedure.

Management

When to intervene?

The rate of spontaneous stone passage in pregnancy is between 64% and 84% [17, 21]. Up to 50% of the remaining stones will pass in the postpartum period [17]. Based on these data, the guiding principle of therapy remains that of conservative management. Conservative management requires hydration, antibiotics, antiemetics, analgesics, and close daily follow-up during the symptomatic period. Straining of urine is also advised. Medical expulsive therapy cannot be recommended as

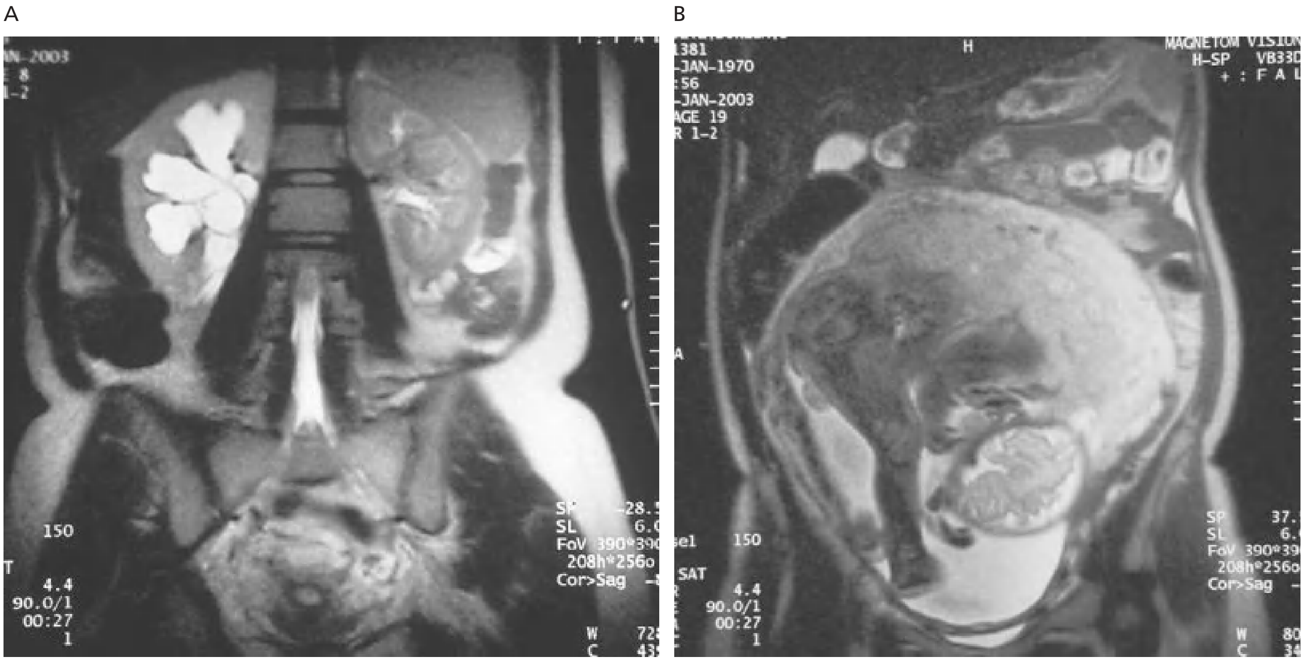

Figure 56.4 (A, B) MR images from a 25-year-old pregnant woman, G1P0 GA 26 weeks, suggestive of right renal calculus based on secondary signs.

part of conservative management, as alpha-blockers, calcium channel blockers, and corticosteroids are contraindicated in pregnancy [47].

Conservative management of urolithiasis will fail in approximately 15–30% of pregnant women [48]. Indications for intervention in symptomatic pregnant patients are the same as in the nonpregnant population. These include sepsis, renal failure from obstruction of a solitary kidney or bilateral obstruction, uncontrolled pain, premature onset of labor, pre-eclampsia, and poor access to expert urologic care.

Anesthetic risks

Use of anesthesia for nonobstetric surgery during pregnancy has a potential for inducing fetal congenital malformations, spontaneous abortion, and premature labor [49]. Thus, nonemergency surgery during pregnancy should not be performed. Open surgery should be considered only as treatment for septic patients who have failed to respond to any other therapeutic options and when endourologic expertise or equipment is not available [48, 50]. Performing any surgery during the first trimester was found to increase risk of miscarriage [51] and in the third trimester of premature labor [52]. The optimal time for performing nonobstetric surgical intervention during pregnancy is the second trimester [52].

In general, the dosing of both general and locoregional anesthetics during pregnancy is decreased [53, 54]. The increased levels of progesterone and endorphins that have been documented in pregnancy probably play a role in decreasing the minimal alveolar concentrations of the inhalational agents halothane and isofulrane [53], whereas progesterone has also been reported to enhance neuronal membrane sensitivity to local anesthetics [54], thereby diminishing the dose. Drug dosing for spinal and epidural anesthesia was reported to diminish even further in the later stages of pregnancy due to compression of the cerebrospinal space and subsequent epidural venous congestion [55].

Any surgical intervention during pregnancy should involve the obstetric team, for monitoring of the fetal heart rate and uterine activity. Fetal monitoring should continue for 24 h post intervention [56]. NSAIDs should not be used for analgesia as they may induce premature closure of the fetal ductus arteriosus [57].

Endourologic interventions

Ureteric stenting

Ureteral stenting represents a temporizing measure, with definitive management deferred until the postpartum period. This approach minimizes or eliminates the requirement for anesthesia, but has several drawbacks. Stent insertion can be accomplished using either fluoroscopy or ultrasound. Fluoroscopy is preferable, but is associated with exposure to ionizing radiation. If using fluoroscopy, fetal shielding and pulsed imaging can reduce radiation exposure. Ultrasound-guided insertion

of a ureteric stent eliminates radiation exposure completely [58].

The main drawbacks of ureteric stenting during pregnancy are stent discomfort and stent encrustation. Stent discomfort is similar to that in the nonpregnant population and can manifest as an increase in urinary frequency and urgency, dysuria, mild gross hematuria, and flank pain. Stent discomfort in pregnancy is usually heightened secondary to presence of overactive bladder symptoms that many women experience in the later stages of pregnancy. The risk of stent encrustation during pregnancy is increased secondary to hypercalciuria and hyperuricosuria of pregnancy. This increased risk necessitates frequent stent exchanges, every 4–6 weeks [18, 59]. The cumulative risks of frequent stent exchanges may exceed that of a single definitive procedure.

Indications for a percutaneous nephrostomy

A percutaneous nephrostomy (PCN) tube is also a temporizing measure that provides immediate and efficient decompression of the urinary tract. PCN insertion can be achieved with ultrasound guidance and under local anesthesia (usually inserted by an interventional radiologist). The main advantages of this treatment modality are absence of ionizing radiation, minimal anesthesia requirements, avoidance of ureteral manipulation, and very effective drainage of the urinary tract. It also establishes a percutaneous tract for later definitive management of calculi. These attributes often make PCN insertion a preferred option for treatment of septic patients or patients during the first trimester [18, 50].

The main disadvantages of PCN tubes are the risk of bleeding during insertion, bacterial colonization, tube dislodgement, blockage by debris, and tube discomfort. PCN tube blockage, encrustation, and dislodgement necessitate PCN exchanges every 6–8 weeks as a preventative measure.

Ureteroscopy

At present, ureteroscopy is considered the procedure of choice in the management of symptomatic urolithiasis in pregnancy, following the failure of conservative management. Safe and successful ureteroscopic management requires modern endoscopic equipment and sufficient endourologic expertise.

The safety and effectiveness of ureteroscopy in pregnancy has been demonstrated in a number of small series [60–73] (Table 56.6). A recent meta-analysis of published reports has documented the safety of ureteroscopic stone extraction or intracorporeal lithotripsy in pregnant women to be equal to that in the nonpregnant population, and complication rates have been low (0–20%) [74].

Ureteroscopy can be performed under general or spinal anesthesia. Intravenous sedation with fentanyl and propofol has also been described. The patient is positioned in the modified dorsal lithotomy position

Table 56.6 Summary of studies of ureteroscopic management of urolithiasis during pregnancy.

[61–63]. Both rigid and flexible ureteroscopes can be used, with instruments sized 8F or smaller, which do not require the dilation of the ureteric orifice [64–66]. Ureteroscopy can be performed either with ultrasound guidance or with pulsed fluoroscopic imaging and mandatory fetal shielding. Performing ureteroscopy in pregnancy is not considered technically difficult, as physiologic dilation of the ureter helps with the manipulation of flexible ureteroscopes [67].

The holmium : YAG laser has emerged as the preferred and safest intracorporeal lithotripter utilized in pregnancy [68, 69]. The holmium : YAG laser has a wide safety margin due to its unique wavelength (2100 nm) and limited depth of penetration in a fluid environment (< 0.5 mm from the tip of the probe). Use of the holmium : YAG laser was reported to result in an 89% overall stone-free rate [68]. A theoretical concern with its use is the production of cyanide during laser lithotripsy of uric acid stones. However, there are no published reports of cyanide toxicity to date [74, 75]. The risk of cyanide toxicity should be negligible, as any cyanide produced during the lithotripsy should be diluted out from the urinary tract with the irrigant.

Alternative intracorporeal lithotripters used in pregnancy include the ballistic or pneumatic lithotripter, ultrasonic lithotripter, and forceps crushers [76–78].

Ultrasonic lithotripsy is known to be very safe to the surrounding tissues [79], but there is a theoretical concern regarding fetal auditory development. However, there is evidence to suggest that the peak pressure of the sound emitted by all intracorporeal lithotripters within the ureter does not affect fetal auditory development [80]. The main limitation of ultrasonic lithotripsy remains the rigid nature of the probe that restricts its use to rigid or semi-rigid ureteroscopes.

The electrohydraulic lithotripter (EHL) has the lowest margin of safety for use in pregnancy. EHL generates high peak pressures and the electrical energy generated from the probe poses a potential risk for fetal injury and induction of premature labor. It is not recommended for use in pregnancy [81, 82].

The potential risks of ureteroscopy are similar to those in the nonpregnant population and include urinary tract infection, sepsis, ureteral perforation, and ureteral avulsion. In experienced hands and with use of proper equipment the complication rates are very low (Table 56.5).

Percutaneous nephrolithotomy

Percutaneous nephrolithotomy (PCNL) is not advised during pregnancy. The necessity of prolonged general anesthetic, prone positioning, and need for fluoroscopy make PCNL a high-risk procedure during pregnancy. PCNL should be deferred until after delivery.

Extracorporeal shock-wave lithotripsy

Extracorporeal shock wave lithotripsy (SWL) is presently contraindicated in pregnancy due to the potential adverse effects of high-energy shock waves on the fetus and the ionizing radiation exposure. However, treatment of six unknowingly pregnant women was not found to result in fetal malformations or chromosomal anomalies in the children [83].

Conclusions

The safe and effective management of calculi in pregnancy requires a thorough knowledge of anatomic and physiologic changes that occur with each stage of pregnancy. Both fetal and maternal health must be considered. The use of ionizing radiation has to be minimized. Clinicians must use a team approach and adhere to strict indications for intervention in order to maximize a successful outcome for the mother and fetus.

CHAPTER 57

Management of Stones in Obesity

Ömer Levent Tuncay, Cenk Acar & Saadettin Eskicorapci
Pamukkale University School of Medicine, Department of Urology, Denizli, Turkey

Introduction

Recent data from epidemiologic studies suggest that the prevalence of overweight and obese individuals has significantly increased from 15% to 30% over the past 20 years [1]. Obesity is a major public healthcare problem. The body mass index (BMI) is an objective measure of obesity and patients with a BMI greater than 40 kg/m^2 have an extremely high relative risk of comorbid diseases: hypertension, diabetes mellitus, hyperlipidemia, hypercholesterolemia, and cardiovascular disease [2]. Additionally, large population-based studies have shown that obesity and weight gain increase risk of kidney stone formation due to alterations in urinary metabolite excretion in adults [3, 4]. In an interview-based study of patients with urolithiais, the prevalence of obesity was 17.2–19.3% [5]. The management of obese stone formers is now safer and more successful thanks to advances in minimally invasive techniques and improvements in anesthesia, but these patients still present some specific technical challenges which the urologist needs to be aware of to provide optimum care.

Obesity and stone risk

Studies have shown that the most common stone component in obese patients is calcium oxalate and they have a slightly higher incidence of uric acid stones as well [4, 6]. In addition, these studies suggest that obesity is strongly associated with an increased risk of stone episodes. Several factors have emerged as causes of stone formation in obesity.

Urine pH

Urinary pH is an important factor in stone formation. Li *et al*. demonstrated that urine pH is inversely related to BMI among obese patients with urolithiasis: mean urine pH in normal body weight, overweight, and obese patients was 6.25, 6.14, and 6.00, respectively [7]. Hyperinsulinemia, insulin resistance, and gout diathesis may be factors that lower urinary pH in obesity.

Hyperinsulinemia

Obese patients have a higher incidence of diabetes mellitus, which correlates with hyperinsulinemia or insulin resistance. Insulin is known to stimulate the synthesis of ammonia and sodium–hydrogen exchange in the renal tubule, which mediates ammonium excretion in urine. Hyperinsulinemia-associated obesity contributes to the development of calcium stones by decreasing urinary citrate and increasing urinary excretion of calcium, uric acid, and oxalate [8]. Insulin resistance may result in defective ammonium production and the ability to excrete acid, thus lowering urine pH.

Metabolites

High metabolic load is another important factor for urolithiasis in obesity. Powell *et al*. demonstrated that increased urinary concentrations of sodium, oxalate, uric acid, phosphate, and cystine were found in obese

Smith's Textbook of Endourology, Third Edition. Edited by Arthur D. Smith, Gopal H. Badlani, Glenn M. Preminger, Louis R. Kavoussi.

patients compared with nonobese counterparts, and these urinary changes were mostly seen in obese women [4]. Taylor and Curhan reported that obese male patients excreted more urinary oxalate, calcium, uric acid, sodium, and phosphate than nonobese patients, as did obese women patients, although increased urinary calcium was seen only in younger women. An inverse relationship between BMI and urine pH was seen also in both men and women [9].

Inhibitors

Urinary citrate excretion is determined by acid–base status and therefore the intracellular pH of renal proximal tubule cells [10]. Acid load promotes proximal tubular reabsorption of citrate and reduces citrate synthesis. Thus, the lower urinary pH commonly seen in obese patients leads to hypocitraturia. Magnesium complexes with oxalate, thereby potentially reducing oxalate absorption in the gastrointestinal tract. Consequently, high metabolic load and decreased excretion of inhibitors such as citrate and magnesium facilitate urolithiasis in spite of increased urinary volume [11].

Diet and medical therapy

Regarding the negative effects of comorbid disease and urolithiasis on kidney function, together with the limitations of stone surgery, medical management of stone disease is the most important goal for preventing further recurrences in morbidly obese patients.

Dietary modifications and weight loss

Dietary modifications can reduce urinary excretion of stone constituents or increase urinary inhibitors. Dietary changes alone may be sufficient to prevent stone recurrence without the need for drug therapy in low-risk stone formers; also, dietary modifications should always accompany drug therapy in patients at high risk of recurrence. Weight loss and dietary modifications, such as increasing fluid and fiber intake, restricting intake of red meat, salt, and oxalate, and only moderate calcium intake, may alleviate urinary electrolyte changes in some patients [12]. Ekuro *et al*. found that appropriate dietary modification and tailored medical treatment successfully lowered the recurrence rate of stone disease in obese patients [13]. In general, patients are recommended to consume enough fluid to maintain a urine output of at least 2 L/day.

Potassium citrate and urine pH modifications

Potassium citrate acts by providing an alkali load and probably reducing urinary calcium. It increases urinary pH and citrate, thereby increasing urinary inhibitory activity. Potassium citrate can be used in hypocitraturic patients and normocalciuric calcium stone formers, regardless of other associated abnormalities. In a randomized trial, potassium citrate was shown to reduce stone recurrence rates by 75% among hypocitraturic stone formers [14]. In patients with gouty diathesis, potassium citrate raises urinary pH and reduces uric acid-induced calcium oxalate stone formation. It has been shown to be effective in reducing stone recurrence rates for patients with hyperuricosuric calcium oxalate nephrolithiasis and lack of tolerability for allopurinol [15]. Increasing the urine pH to above 5.5 and preferably between 6.5 and 7.0 plays a key role in the management of gouty diathesis [16]. Potassium citrate should be given at a dose sufficient to maintain the urine pH at approximately 6.5. Alkalinization of the urine to a pH higher than 7.0 should be avoided as this will increase the risk of calcium phosphate stone formation.

Potassium citrate is prescribed at a starting dose of 10 mEq three times daily, or 20 mEq twice daily. It is prescribed along with a thiazide diuretic or indapamide to reduce the risk of thiazide-induced hypokalemia and hypocitraturia in patients with hypercalciuria. For patients with enteric hyperoxaluria, potassium citrate therapy can raise urine pH and citrate, and for these patients can be given in dosages higher than those used for idiopathic calcium nephrolithiasis (up to 120 mEq/day).

Allopurinol

Two pharmacologic approaches to the management of hyperuricosuric calcium oxalate nephrolithiasis are decreasing the production of uric acid and altering the urinary milieu for uric acid in a dissolved state. Allopurinol (300 mg/day) may be given to patients who are unable or unwilling to comply with dietary protein restriction. Diluting urine to maintain uric acid at a low concentration and the use of an alkalinizing agent such as potassium citrate (30–60 mEq/day) may promote dissolution of uric acid.

Interventional therapies

The American Urological Association (AUA) clinical guidelines for urolithiasis indicate that spontaneous stone passage is seen in between 10% and 53% of patients with stones of 6–10 mm [17], indicating that patients with a stone size larger than 5 mm may encounter some stone-related complications, such as renal colic, urinary obstruction, and infection, and may require interventional therapies. However, obesity poses a number of problems in the management of stone disease from diagnosis and imaging through to anesthesia and

surgery. Beyond these pitfalls, treatment success of interventional therapy is negatively influenced by obesity as well, although some technical modifications have been reported to increase the success rates. Below, the basic features of these therapies in obese patients are emphasized.

Extracorporeal shock-wave lithotripsy

Extracorporeal shock-wave lithotripsy (ESWL) has been widely used as the primary treatment modality for most renal and ureteral calculi [12, 18]. Uncorrected coagulopathy, pregnancy, severe skeletal deformity, and morbid obesity were accepted contraindications of this modality. Advantages of ESWL for renal and ureteral stones are avoidance of anesthesia-related complications and the ability to perform it many times without increasing morbidity. However, optimal ESWL treatment in obese patients is restricted by the table's weight limit (135 kg for the Dornier HM3) and the short focal length (12–14 cm) of lithotripters [19]. Treatment success for renal stones of 20 mm or smaller was reported to be above 90%, and 92.6–97.5% for ureteral stones of 10 mm or smaller in the overall patient population [12]. However, Delakas *et al*. suggested that the probability of ESWL failure was increased 1.9 fold in patients with a BMI over 30 kg/m^2 [20]. Munoz *et al*. reported that the success rate of ESWL for renal and ureteral stones was 72% in obese patients [21]. Additionally, Ackerman *et al*. stated that BMI was an independent predictive factor of ESWL failure and patients with a BMI of 28 kg/m^2 or less had better treatment results [22]. Recent studies emphasize the importance of skin–stone distance in stone clearance, measured as the mean value of three distances from the renal stone to the skin at 0°, 45°, and 90° and using a radiographic caliper or computational measuring device [23, 24]. They suggested that a skin–stone distance greater than 10 cm more strongly predicted ESWL failure than BMI or Hounsfield units [25]. The success rates of ESWL for lower calyceal stones are low in obese patients compared to their nonobese counterparts.

Reducing the focal length by using an abdominal strap and selecting lithotripters with long focal length and high energy settings may improve the success rate of ESWL [26]. Additionally, Mezentsev reported that ESWL with "blast path" technique in morbidly obese patients gives better treatment results (87%) even if the stone is located a few centimeters from the center of the focal area [27]. Tips and tricks for ESWL in obese patients are listed in Table 57.1.

Table 57.1 Tips and tricks for shock-wave lithotripsy in obese patients.

Use abdominal strap to reduce the focal length
Choose a long focal length lithotripter or high energy setting
Use "blast path" technique when the stone is located a few centimeters from the center of focal area

Ureterorenoscopy

Owing to recent technologic advances, retrograde endoscopic lithotripsy for renal and ureteral stones with flexible and semi-rigid ureterorenoscopy (URS) has become a feasible treatment option. According to the European Association of Urology (EAU)/AUA Guideline Panel on ureteral stones, URS gives a superior stone-free rate in proximal ureteral stones larger than 1 cm, and in all mid-ureteral and distal stones when compared with ESWL [18]. Additionally, URS can be safely performed in special circumstances, such as pregnancy, children, ectopic, pelvic or transplant kidneys, and patients on anticoagulation medication. Although ESWL is the accepted first-line treatment modality for renal stones (<2 cm), it may be precluded by the weight limitations of the treatment table and difficulties in focusing on the stone due to impaired radiologic imaging (fluoroscopy or ultrasound) and short focal length [28]. Flexible URS is indicated in renal stones of less than 15 mm that do not respond to ESWL [29]. Dash *et al*., in a stone-matched comparison (obese vs nonobese), reported that URS treatment for renal calculi was effective in obese patients as well as nonobese counterparts without increasing morbidity [30]. In a recent study in 107 patients, Natalin *et al*. evaluated their URS treatment outcomes for renal and ureteral stones according to BMI, and stone size and location. Overall stone-free rates were 91%, 97%, and 94% in normal weight, overweight, and morbidly obese patients, respectively. They found no significant difference in terms of stone location (renal/proximal, mid-, and distal ureteral stones) and size (cut-off dimension was 1 cm) in all groups. Consequently, they emphasized that URS treatment is an acceptable modality for all ureteral calculi with a high success rate in obesity, and it may be preferable to ESWL for obese patients [31].

Generally, additional technical modifications are not recommended when performing URS in obese patients. To prevent further interventions, recent developments in URS treatment, such as digital flexible URS, ureteral access sheaths, holmium laser lithotripsy, and nitinol stone baskets, may be used [32]. Flexible URS may guide percutaneous renal access in obese patients or when a previous attempt has failed. Khan *et al*. described a technique in which a flexible URS was advanced to the intended calyx with the patients in a prone split-leg position, and percutaneous calyceal puncture was performed under direct vision [33].

Percutaneous nephrolithotomy

Percutaneous nephrolithotomy (PCNL) is recommended for kidney stones larger than 2 cm and for staghorn calculi [34]. PCNL is also indicated in cases of SWL failure, stones with concurrent ureteropelvic junction obstruction, stones within calyceal diverticuli, and anatomic abnormalities (e.g. horseshoe kidney). The absolute contraindications are active urinary tract infection and uncontrolled coagulopathy. Studies suggest that the success and complication rates of PCNL in obese patients are comparable with those for the normal weight population [35–37]. Pearle *et al*. found that the stone-free rates for staghorn and nonstaghorn stones in obese patients were 84.2% and 90.2%, respectively [35]. Of these patients, 14% had minor or major complications and 8.8% needed blood transfusion, and their mean hospital stay was 4.9 days. The authors also reported that technical modifications and appropriate instrumentation were necessary to improve the stone-free rate in this group of patients. Similarly, El-Assmy *et al*. reported their 4-year experiences of PCNL in 1121 patients. The stone-free rate for obese patients was 84.7%. Hematuria requiring blood transfusion (3.2%) and septicemia (2.1%) were the most common major complications in the obese and morbidly obese group. The complication rate and length of hospital stay were similar to those for the nonobese group. They concluded that PCNL is a feasible and effective procedure in obese and morbidly obese patients as well as nonobese counterparts [36].

Traditionally, PCNL has been performed in the prone position. This position facilitates posterior access to the collecting system through Brodel's avascular renal plane without causing significant parenchymal bleeding, peritoneal perforation, and visceral injuries. However, prone PCNL often causes respiratory system problems due to restriction of the patient's chest movement, and surgery may not be sustained in this position. The anesthesiologist and surgeon generally struggle to use this posiion in morbidly obese patients due to compromised cardiopulmonary status and body weight.

Increased knowledge of renal anatomy and clinical experience with PCNL have encouraged urologists to modify the prone position in an effort to improve results and overcome these limitations. The more recent literature has focused on alternatives in patient positioning, widening patient selection, or new techniques (i.e. tubeless PCNL). Gofrit *et al*. described lateral decubitus positioning for PCNL in morbidly obese or kyphotic patients [38]. Valvadia *et al*. first described PCNL in the supine position for patients with high anesthesiologic risk [39] and several authors have reported their experiences [40–45] (see Chapter 10). The supine position has several advantages, such as decreasing anesthetics requirement, preventing respiratory system-related complications, and allowing a simultaneous retrograde URS approach. In addition, urologists are more comfortable adopting a sitting posture during stone management. Difficulties in filling the collecting system against gravity, the small surgical field for nephroscopic maneuvers, difficulties in advancing the needle into the upper calyx are some limitations of supine PCNL. A randomized prospective study comparing the outcomes of PCNL in the supine and prone position reported treatment success rates of 77% and 80%, respectively [46]. In a comprehensive review, de la Rosette *et al*. emphasized that prone PCNL appears to be the more feasible with decreased operative times, similar bleeding rates, and slightly better stone-free rates than supine PCNL [47]. In contrast, Manohar *et al*. reported that the stone-free rate of supine PCNL in high-risk and morbidly obese patients was 95% [42]. Although the supine position seems to have some advantages for obese and morbidly obese patients and patients with staghorn calculi, the prone position has better outcomes over the supine position.

Percutaneous access into the pelvicalyceal system can be more difficult in obese patients. Some modifications have been reported to overcome this difficulty. Grasso *et al*. reported a technique of passing a flexible ureteroscope to capture the percutaneously inserted guidewire and establish through-and-through access at the beginning of the procedure [48]. Additionally, morbidly obese patients generally have excessive subcutaneous and fatty tissues and as a result standard PCNL instruments are too short to reach the stone. Segura described a technique to incise the skin and fat, with incision extending down to the muscular fascia, reducing the length required to reach the stone [49]. Giblin *et al*. reported the use of a long Amplatz sheath in combination with a 30F gynecologic laparoscope, which has a working length of 27 cm, to treat stones in morbidly obese patients [50]. In addition, choosing the shortest tract for percutaneous access and using longer devices, such as an Amplatz sheath longer than 17 cm and longer nephroscope, may facilitate the procedure. Moreover, using a ureteroscope through the percutaneous site may be helpful. Another technical problem specifically encountered in obese patients is the migration of the Amplatz sheath beneath the skin or muscle fascia (Figure 57.1). Bugeja *et al*. described a simple technique that makes use of a modified 10-mL syringe barrel to facilitate retrieval of a migrated access sheath in obese patients during PCNL [51]. We recommended using two sutures on the Amplatz sheath to prevent it from lodging under the skin (Figure 57.2). In this situation, these sutures allow the sheath to be pulled back out of the skin, either manually or using the open jaws of the grasping forceps (Figure 57.3). If all these techniques fail, a Foley catheter can be inserted into the sheath (Figure 57.4), and the sheath then pulled out after

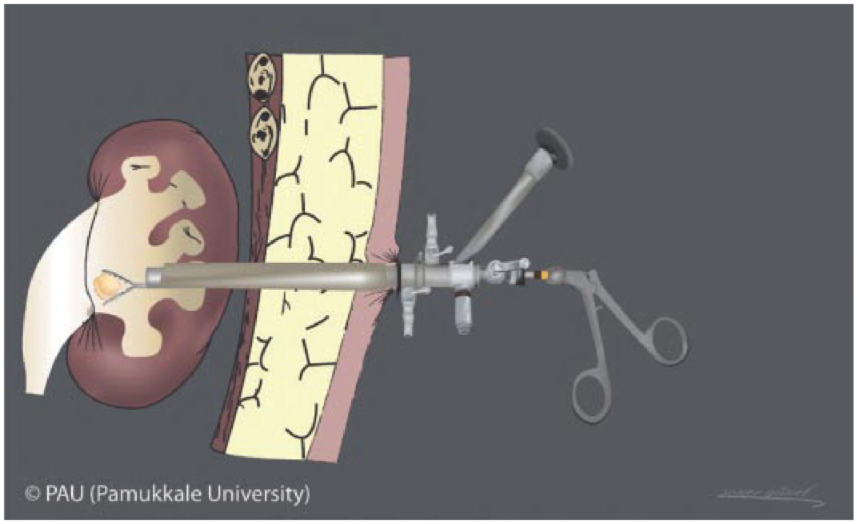

Figure 57.1 Migration of the Amplatz sheath beneath the Skin during percutaneous nephrolithotomy in an obese patient.

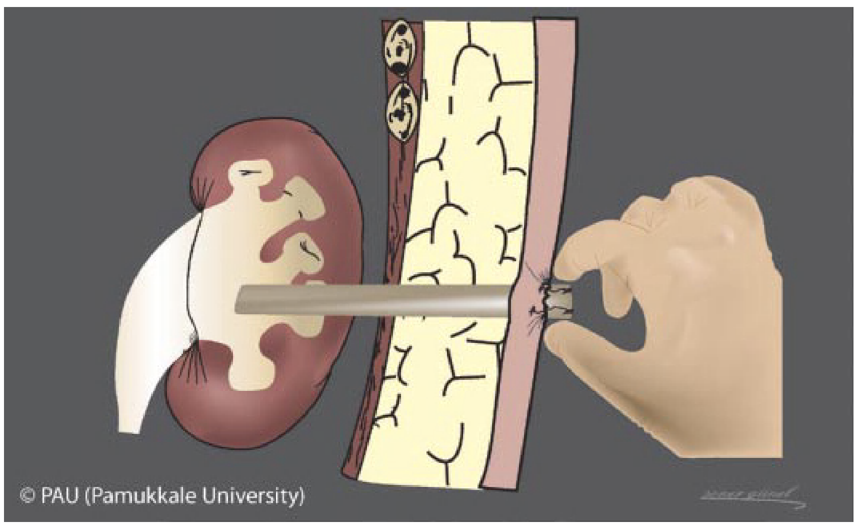

Figure 57.2 Two sutures on the Amplatz sheath help prevent it from becoming lodged under the skin.

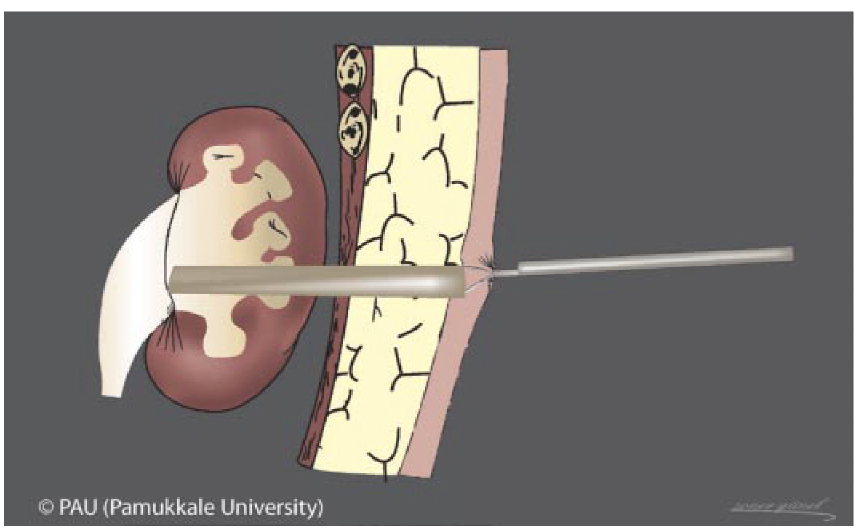

Figure 57.3 Using the open jaws of grasping forceps to retrieve the Amplatz sheath.

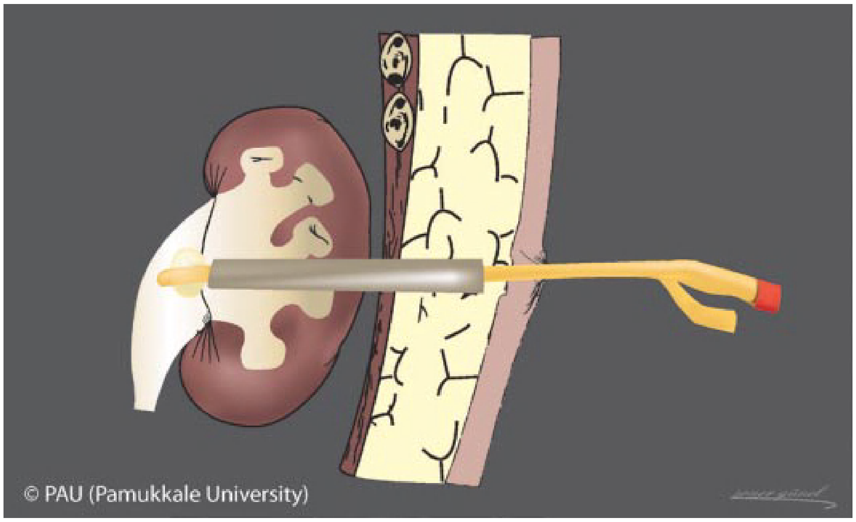

Figure 57.4 Inserting a Foley catheter into the Amplatz sheath facilitates withdrawal of the sheath once the balloon has been inflated.

Table 57.2 Tips and tricks for percutaneous nephrolithotomy in obese patients.

Use long Amplatz sheaths and nephroscopes
Choose the shortest possible tract
Stitch two sutures on the Amplatz sheath
Use the supine position in selected patients (for ventilation problems)

inflating the balloon. Tips and tricks for PCNL in obesity are listed in Table 57.2.

The surgical steps of standard prone PCNL in an obese patient are demonstrated in Video 57.1.

Conclusions

Epidemiologic studies indicate that obesity increases the risk of urolithiasis. Several pathophysiologic mechanisms have been proposed for abnormalities in urine composition in obese patients. These include carbohydrate-induced calciuria, increased protein intake, effects of insulin resistance on renal ammonia metabolism and urine pH, increased prevalence of gout and hyperuricosuria, or some other unidentified abnormality in renal electrolyte transport. Dietary modifications have an important role because metabolic abnormalities are more common in obese stone formers. Medical treatment has been shown to reduce the risk of stone formation.

Obesity poses a number of problems in the management of stone disease from diagnosis and imaging through to anesthesia and surgery. Comorbidity will be increased and anesthesia will need special expertise in this group of patients. ESWL has some limitations in morbidly obese patients in terms of table weight limit and focusing the stone. Several techniques have been described to overcome these limitations in some patients. Flexible URS technology is gaining worldwide acceptance because it allows rapid and high stone clearance rates. The PCNL technique can be modified in obese patients, providing similar outcomes and morbidity to those in nonobese patients. To manage the obese patients with urolithiasis safely and effectively, the urologist should have knowledge and experience of the potential diagnostic and treatment problems, as well as modifications of the techniques.

CHAPTER 58
Management of Residual Stone Fragments

Andreas Skolarikos
Athens Medical School, 2nd Department of Urology, Sismanoglio Hospital, Athens, Greece

Introduction and definitions

Residual stone fragments (RFs) represent a common and still controversial problem of shock-wave lithotripsy (SWL), percutaneous nephrolithotomy (PCNL) and ureteroscopy (URS). Still, the definition of RFs has not been well established. In the era of open stone surgery, RFs of any size suggested a failed procedure. With the advent of SWL, all fragments remaining in the kidney 3 months after the last session of SWL are defined as RFs [1]. Fragments larger than 5 mm are generally considered to indicate a failure of SWL [2]. Any fragments remaining following PCNL or URS are considered as RFs. The issue of RFs becomes more complicated with the introduction of the term "clinically insignificant residual fragments (CIRF)." The definition of CIRF that has prevailed describes post-treatment stones that are smaller than 4–5 mm, asymptomatic, nonobstructive, noninfectious, and associated with sterile urine [2–4]. The choice of size limit of less than 4–5 mm has not been based on solid statistical observations from previous studies.

RFs may be important for several reasons. They may act as a nidus for recurrent stone growth, especially when underlying metabolic abnormalities persist; they can become dislodged acutely and cause significant obstruction with pain; or they may be the source of persistent infection [3]. In patients with infection-related calculi, the consequence of RFs can be particularly harmful. RFs may harbor the offending bacteria and thus perpetuate postoperative bacteriuria and persistent infection. Furthermore, stone regrowth has been reported in up to 75% of such patients after SWL, compared with 10% of patients who experienced complete stone removal [5, 6]. For patients with metabolic stone disease, complete stone removal does not prevent stone recurrence, but it does prolong treatment intervals [7]. Thus, residual stones in these categories, including small stones, may not have an immediate clinical relevance but are likely to affect a patient's well-being in the long term. In these situations, it is important to select the treatment approach that is most likely to render the patient stone free.

We will review the natural history, identification, and treatment options for RFs following SWL, PCNL, and URS in the modern endourologic era.

Residual stone fragments following shock-wave lithotripsy

Outcome

Several studies have stressed the fate of RFs after SWL (Table 58.1) [5, 6, 8–15]. For a mean follow-up range between 6 and 57 months, spontaneous stone passage was noted in 11–92.7% of cases. The spontaneous clearance rate was highest for stones located in the ureter and lowest for the lower pole stones. Stones remained stable in 11–52.6%, while stone regrowth was encountered in 2–78%. This wide spectrum of results is attributed to the nature of the studies, most of which presented retrospective experiences. In addition, there were differences in the studies between methods of reporting treatment

results, radiologic evaluation of residual stones, site and size of the residual stones, and timing of record of patients' follow-up data (1 vs 3 months) after the last session of SWL.factors Rassweiler *et al.*, in an extensive review of the literature, reported that 25% and 55% of patients with CIRF would be stone-free or the CIRF remain clinically insignificant during follow-up, respectively, 20% of CIRF would become clinically significant, and 4–25% of patients would require a secondary intervention which mostly would consist of a repeat SWL. The authors concluded that if there are no clinical symptoms, any endoscopic procedure should be considered as overtreatment [4].

The natural history and clinical significance of small, asymptomatic, noninfection-related stone fragments after SWL were prospectively evaluated in four studies [9, 10, 12, 14]. In total, 463 patients with CIRF of less than 5 mm in diameter were prospectively followed for a mean period of 15 months [12] to 4.9 years [14]. Stone-free status or a stable or increased amount of residual stone ranged from 23.8% to 78.9%, 10.7% to 41.9%, and 2% to 58.6%, respectively, and 41.4–100% of patients remained asymptomatic, while 0–58.6% had a symptomatic episode or required intervention 1.6–85.4 months after SWL. The intervention required was relatively noninvasive and consisted of either repeat SWL or retrograde endoscopy. As the stone burden and number of stone fragments increased, and when the fragments were located in the lower calyces, the risk of CIRF becoming clinically significant increased [9, 12, 14]. Also, as the duration of follow-up increased, the rate of complications increased [12]. Metabolic defects, when treated adequately, did not increase the regrowth rate [12, 14]. The results of these studies indicate that while patients with small CIRF after SWL can be followed expectantly, a significant number will require intervention or have symptomatic episodes during follow-up. As a consequence, the term CIRF after SWL may not be appropriate.

Diagnosis

There are no widely accepted guidelines regarding post-SWL imaging and follow-up. For radio-opaque stones, most urologists order a kidney, ureter, and bladder (KUB) X-ray, and for radiolucent stones a computed tomography (CT) scan or ultrasound is required. The timing of post-SWL imaging also varies widely from center to center. Many endourologists feel that there is no role for routine imaging less than 3 months post SWL because stone fragments may take several weeks to pass after SWL. Unenhanced helical CT (UHCT) has been shown to be superior to other imaging modalities in its ability to identify the presence of urinary calculi in general. In a prospective study, CT had a sensitivity of 97%, specificity of 96%, and accuracy of 97% for revealing urinary stones [16].

Data from several prospective studies of UHCT overwhelmingly support CT as the best method for diagnosing the presence of urinary stones when compared to ultrasound, ultrasound combined with plain X-ray films, intravenous urography (IVU), and magnetic resonance urography (MRU) [17–21]. A recent meta-analysis showed that CT scan is better than IVU for the detection of urinary stones. There is little difference in the radiation dose and patient acceptability for each test [22, 23].

The ability of UHCT to detect small renal calculi is significantly affected by section width, particularly when stone fragments are smaller than 3.0 mm. Section widths of 1.25 and 2.5 mm were able to show renal stones significantly better than thicker reconstructions. Specificity was not significantly affected by section width in a recent study of Jin *et al.* [24]. In contrast, sensitivity increased as stone size increased and as

section width decreased. Sensitivity for the detection of all stones was 80.7%, 80.7%, 87.7%, and 97.7% for 5.0-, 3.75-, 2.5-, and 1.25-mm section widths, respectively. Nevertheless, thinner section widths create more images for evaluation and increase image noise, potentially increasing the false-positive rate [24].

When an RF is found, CT can also provide excellent information about its size, location, and composition, providing the urologist with critical information for planning treatment. Therefore, it can be suggested that the literature supports that CT be utilized in preference to other imaging modalities for patients with suspected RFs following SWL. Improvements in CT technology with the development of low-dose protocols, dual-source CT, and micro CT, while maintaining quality of imaging for diagnosing stones, will eventually replace other imaging modalities in the diagnosis of RFs following SWL [25–27].

Surgical management

In the past, several authors have not recommended systematic SWL retreatment for all asymptomatic patients with RFs after an initial session of SWL [4, 6, 10, 28]. With the exception of the study performed by Buchholz *et al*. [10], the above recommendation emerged from the results of reviews or retrospective studies. Buchholz *et al.*, in a study of 55 patients with CIRF, showed that only 12.7% of the RFs had not passed spontaneously after a mean follow-up of 2.5 years [10]. All were clinically silent and only in 2% of the cases was stone regrowth seen. No stone recurrences were observed within the follow-up period. The authors concluded that more invasive procedures to clear all minor fragments are not warranted. However, with emerging evidence showing that the term CIRF could be a misnomer, mainly due to the fact that a great proportion of patients will require an intervention as the follow-up increases [9, 10, 12, 14], several authors have addressed the issue of early retreatment of RFs after an initial intervention [8, 29–32].

Parr *et al*. in a retrospective study showed that additional SWL for CIRF remaining after a mean of two (range one to nine) initial SWL sessions, promoted stone clearance only in those patients with nondilated calyces [29]. The small number of patients included in the study (n = 22), the small number of patients who benefited from retreatment (n = 3), and the nature of the study do not allow definitive conclusions to be drawn. In a retrospective study by Moon *et al.*, the stone-free rate for 248 cases of CIRF was 32.7% at 1 month, 73.0% at3 months, and 92.7% at 6 months of follow-up [8]. Of 16 patients who had RFs at 6 months and who underwent an additional session of SWL, 12 (75%) became stone free by another 6 months of follow-up. The authors suggested that repeated SWL, even for stone fragments of 3–4 mm in diameter, might promote clearance of the CIRF. This was confirmed in a prospective randomized study conducted by Krings *et al*. [30]. Piezoelectric SWL retreatment was compared to surveillance only in 50 patients with persistent calyceal stone fragments after primary SWL for renal calculi. After 3month follow-up, significant decreases in residual debris were observed in the retreated group, while changes in the control group were negligible. The authors suggested that, considering the low morbidity of outpatient SWL with a pain-free, second-generation lithotripter, SWL retreatment of completely fragmented but persistent stone debris appears to be justified to render the kidney stone free. Still, the advantages of a higher stone-free rate from SWL retreatment must be weighed against potentially higher side effects and the additional cost.

An adjunct to the clearance of lower pole calculi after SWL has emerged in the form of mechanical percussion and inversion with or without diuresis [33]. In this study by Chiong *et al*., 108 patients with lower pole calculi of 2 cm or smaller were prospectively randomized to undergo SWL alone or SWL followed by mechanical vibration, inversion, and diuretic therapy [33]. The radiologically documented complete stone clearance rate at 3 months for the first group was 35.4%, while for the second group it was 62.5% ($P = .006$). The same treatment modality has been applied in a prospective randomized manner for CIRF after SWL [31]. Pace *et al*. compared the effectiveness of mechanical percussion and inversion with observation for 1 month, for eliminating calyceal fragments of less than 4 mm 3 months after SWL. The mechanical percussion and inversion group had a substantially higher stone-free rate (40% vs 3%, $P < 0.001$) and a greater improvement in total stone area (–63.3 vs +2.7%, $P < .001$) than the observation group. No significant adverse effects were noted in either group. The authors stated that mechanical percussion and inversion is a safe and effective treatment option for residual lower pole calculi.

Medical treatment

Metabolic evaluation and stone analysis should be offered to patients who require surgical stone removal. Pearle *et al.* have emphasized the importance of the administration of medical therapy in reducing stone recurrences after treatment [34]. In their meta-analysis of randomized trials for medical prevention of nephrolithiasis, they showed a significant benefit of drug therapy for calcium oxalate stones. This was mainly attributed to the benefit of using thiazides compared to placebo or no treatment. The variability in design of the analyzed studies precluded adequate analysis of other drug therapies such as alkaline citrate or allopurinol.

Table 58.2 Effect of medical therapy on residual stone fragment activity.

	Stone free (%)		Stone size unchanged or decreased (%)		Stone size increased (%)**

†Study in children.

Medical therapies, in addition to preventing stone recurrences, have been reported to ease urinary stone passage [35]. Hollingsworth *et al.* have published the results of a meta-analysis of all randomized controlled trials in which calcium channel blockers or alpha-blockers were used to treat urinary stone disease [35]. Their findings, extracted from nine trials encompassing 693 patients, suggested that medical therapy is an option for facilitating urinary stone passage for those patients amenable to conservative management, potentially obviating the need for surgery. Patients given calcium channel blockers or alpha-blockers had a 65% greater likelihood of stone passage than those not given such treatment. The pooled risk ratio for alpha-blockers was 1.54 (1.29–1.85) and for calcium channel blockers with steroids was 1.90 (1.51–2.40). The proportion of heterogeneity not explained by chance alone was 28%. The number needed to treat was 4.

Several authors have addressed the issue of medical therapy in the management of RFs after SWL [36–39] (Table 58.2). Fine *et al.*, in a retrospective nonrandomized study, evaluated the fate of RFs after SWL in regard to whether the patients were or were not put on medical therapy after the procedure [36]. Of the 49 patients identified with RFs after SWL, 36 received medical therapy in the form of thiazide diuretics, sodium cellulose phosphate, allopurinol, potassium citrate, and α-mercaptopropionylglycine, based on specific indications. Thirteen patients chose to stop medical treatment within 4 months after SWL. Patients on medical therapy experienced a significant decrease in the stone-formation rate from a median of 1.17 to 0.00 stones/patient/year ($P < .001$). In those patients not on medical therapy, there was only a minimal decrease in the stone-formation rate from a median of 1.33 to 0.77 stones/patient/year. The medically treated patients had a significantly greater stone remission rate than the untreated patients (63.9% vs 23.1%, $P < 0.05$), while stone burden increased in 27.8% and 61.6%, respectively. Moreover, while 13.9% of the treated patients demonstrated a decrease in stone burden, none of the untreated patients showed a decrease in stone mass. The authors specifically assessed the significance of CIRF (stones < 5 mm in diameter). Among the 49 patients, 36 had CIRF, and 25 of these received medical therapy while 11 did not. Fragment growth was seen in 16% of those treated medically compared to 54.5% of the untreated patients ($P < .05$). This retrospective study indicated that early medical therapy may control active stone formation in patients with RFs following SWL [36].

These results were confirmed by three prospective randomized trials. Cicerello *et al.* showed that citrate intake reduced growth or agglomeration and increased the clearance rate of RFs after SWL in calcium oxalate and in infection stone patients [37]. The authors prospectively randomized 40 sterile calcium and 30 struvite stone patients with RFs of less than 5 mm in diameter after SWL into two groups: one on citrate therapy (6–8 8 g/day) and the other on hygienic measures only, the latter serving as the control group. Infection stone patients also received adequate antibiotic therapy throughout the study. After 12-month follow-up, RFs disappeared in up to 74% of the citrate-treated calcium oxalate patients and up to 86% of the citrate-treated infection stone patients. In the control group, the rates were 32% and 40%, respectively. During the 12-month follow-up, RF growth or reaggregation occurred in 47% of the calcium oxalate control patients compared to 5% of the calcium oxalate citrate-treated patients. None of the treated or control infection stone patients in whom stone fragments persisted at the end of follow-up had growth or reaggregation of RFs [37].

Similar results were found in the study by Soygur *et al.*, who prospectively randomized 34 patients with lower pole RFs after SWL into two groups that were matched for sex, age, and urinary levels of citrate,

calcium, and uric acid [38]. One group was given oral potassium citrate 60 mEq/day and the other group served as controls. The stone recurrence rate at 12 months in the group who were on citrate therapy was significantly less than in the control group (56.6% vs 87.5%, respectively). Stone fragments disappeared in eight (45.5%) and remained the same size in 10 of the 18 patients (54.5%) who continued medical therapy. In the control arm, RFs disappeared in only two (12.5%) and remained unchanged in four (25%) of the 16 patients [38].

Medical treatment also appears to prevent stone regrowth or stone formation in children with RFs after SWL. Sarica *et al*. randomized 44 children in whom stones of less than 5 mm in diameter persisted after SWL into two groups [39]. Group I (n = 22) received potassium citrate 1 mEq/kg/day for 12 months under close follow-up. Group II (n = 22) received no specific medication or preventive measure and constituted the control group. Children on medication showed significantly lower regrowth and recurrence rates compared to children in group II [four of 22 (18.1%) vs 16 of 22 (72.7%), respectively]. Moreover, the mean size of the RFs in patients receiving no therapy demonstrated a significant increase from baseline compared with the children on medication. Whereas the mean size of the RFs in group II was 3.6 mm 1 month after SWL, it was 5.4 mm after a year ($P < 0.05$). There was no significant change in children undergoing potassium therapy, with mean sizes of 4.0 mm before medication and 4.4 mm at 1 year ($P > 0.05$) [39].

Medical expulsive therapy to enhance the stone-free rate following SWL has recently been questioned. This was triggered by a recent double-blind, placebo-controlled randomized trial which showed that tamsulosin treatment does not improve stone expulsion rate in patients with distal ureteral stones of less than 7 mm [40]. Subsequently, Wang *et al*. randomized 107 patients who had been treated with SWL for lower ureteral stones into three groups. The first group received tamsulosin, the second terazosin, and the third placebo after the SWL. The administration of an alpha-blocker reduced analgesic dosage and colic episodes after SWL of lower ureteral stones. There was no benefit with regard to increasing stone expulsion rate or decreasing expulsion time (Table 58.2) [41]. Large-scale, well-designed randomized studies will eventually elucidate the role of adjunctive medical therapy following SWL.

Residual stone fragments following percutaneous nephrolithotomy

Natural history

Assessment of stone clearance after PCNL is based on the endoscopic appearance of the collecting system at the completion of the procedure [3, 42, 43]. Stone-free rates have been reported to range from 40% to 90%, depending on the size, number, composition, and nature (i.e. staghorn, infectious) of the stone, as well the surgeon's skills [44, 45]. Reasons for failure of complete clearance during PCNL include poor visualization secondary to bleeding, inability to access a fragment-containing calyx, and the subjective impression of prolonged operative time. Improper selection of the surgical technique as well as anatomic abnormalities, stone composition, and technical constraints may influence the number and size of RFs versus a stone-free status [3].

In a study by Ramana *et al.*, of 537 patients who were followed up after PCNL with UHCT, 42 (8%) patients were diagnosed with RFs [42]. The anatomic distribution of RFs was 47% lower, 32% mid, 24% upper pole, and 18% renal pelvis/ureter. The median diameter of the largest RF was 2 mm, with 60% (25 of 42) of fragments 2 mm or smaller and 79% (33 of 42) smaller than 5 mm. All 42 patients with RFs were under surveillance and 18 (43%) of them experienced a stone-related event with a median time to occurrence of 32 months. A stone-related event is defined as growth of a RF or need for emergency consultation, hospitalization, or additional intervention specifically aimed at alleviating symptoms, obstruction, and/or removing the RF. The authors reported that of the 18 patients who experienced a stone-related event, 11 (61%) required a secondary surgical procedure. Fragments with a maximum diameter greater than 2 mm and those located in the renal pelvis or ureter independently predicted a future stone-related event. In addition, more than half the patients with an RF larger than 2 mm required a second-look flexible nephroscopy, underscoring the importance of maximum RF size in comparison with cumulative RF size.

In another study evaluating the fate of residual stones after PCNL, RFs of less than 25 mm^2 and those situated in the renal pelvis again had the best chance of clearance. Approximately half the RFs passed spontaneously, and the majority was cleared in 3 months. The size of the residual stone, history of intervention, renal failure, and metabolic hyperactivity were predictors of persistence of RFs [46].

Significance of residual fragments

The term "CIRF left after PNCL" defines RFs of similar characteristics to CIRF after SWL [3, 47]. Recently, Osman *et al* introduced the term "CT clinically insignificant RFs," including one or two gravels less than 5 mm, as measured by post-PCNL UHCT [48]. We feel that these terms may lead to the acceptance of treatment failures and minimize the clinical significance of RFs after PCNL.

There is no reason to believe that RFs after PCNL will behave differently from RFs after SWL. However, the clinical scenarios are nonetheless significantly different. Removal of RFs after SWL requires either additional SWL or more likely, an invasive surgical intervention. In contrast, removal of RFs diagnosed after PCNL may involve a second procedure (i.e. flexible nephroscopy) through a pre-existing tract. Furthermore, there is theoretical concern that the rate of stone formation may be greater following SWL compared to PCNL because of microscopic residual stone debris left in the collecting system acting as a nidus for stone crystallization. Carr *et al.* demonstrated a significantly greater rate of stone formation within 1 year after treatment with SWL compared to PCNL [47]. Stone recurrences for the SWL group showed a shift from baseline location before treatment to a greater likelihood for recurrence within mid and lower calyces. A similar trend was not observed in the PCNL group. An explanation for these results would be that fine sand debris gravitate to dependent calyces and act as a nidus for stone growth. SWL, by dramatically increasing the surface area of the original stone, may favor new stone growth through heterogeneous nucleation and crystal aggregation.

Prevention

Fragmentation and removal parameters

The impact of single and multiple pulse settings of pneumatic lithotripsy on creating RFs during PCNL has been addressed in a prospective study [49]. The single pulse mode was associated with controlled fragmentation of the stone, formation of larger fragments which were easier to pick up, less stone scatter, shorter operating time (124.1 min vs 141.2 min), less exposure to fluoroscopy (5.8 min vs 7.4 min), and statistically less chance of RFs (16 cases vs 35 cases).

Multitract PCNL for large staghorn stones could potentially reduce the incidence of RFs. Such a technique has been demonstrated as feasible, safe, and effective in a study of 121 renal units with complete staghorn stones [50]. There are a number of graspers and baskets available to snare and remove stones during PCNL. Flushing out the collecting system, once stone fragments have been identified as of a size that can pass through the Amplatz sheath, may further reduce the number of potential RFs [51].

Instruments preventing fragment migration

During PCNL, stone fragment migration remains a concern, especially if it occurs into the ureter, as additional procedures are then necessary. Deploying the Stone Cone® (Boston Scientific, Natick, MA, USA) just below the ureteropelvic junction obstruction has been shown to prevent migration of stone fragments into the ureter during PCNL [52]. This maneuver may reduce the need for antegrade URS to remove RFs, thereby saving time and obviating the need for placement of an occlusion ureteral balloon. It would be interesting to study the feasibility and efficacy of placing such an instrument in those calyces where protection from migrating fragments is particularly desirable, i.e. the upper pole in case of lower pole access.

Diagnosis

Plain X-ray KUB, linear tomography, and ultrasound have all been used to judge the result of PCNL and to detect the presence of RFs. However, the superimposition of bowel gas, feces, and soft tissue calcifications, as well as the presence of obesity, faintly radio-opaque stones, nephrostomy tubes and/or pigtails decrease the accuracy of these diagnostic modalities [3, 53, 54].

When thin-slice UHCT, in conjunction with image reconstruction, was prospectively compared to other imaging modalities, it showed higher sensitivity for the detection of RFs [44, 48, 55]. The sensitivity of the UHCT reached 100% [55] compared to 47.6–82.1% [44, 55] for X-ray KUB, 89.2% for linear tomography [55], and 67.8% for ultrasound [55]. The mean size of stones missed by KUB films was 7.4 mm, with 45.5% of stones being greater than 4 mm in diameter [44]. When the outcome of detecting RFs is stratified by stone density and stone size, UHCT sensitivity appears to be even higher for faint, lucent, and small stones compared to the sensitivity of other imaging modalities [56]. The sensitivity for overall detection of opaque stones was 100%, 62.9%, and 74.3% for UHCT, KUB, and ultrasound, respectively. In contrast, for faint and lucent stones, the rates were 100%, 11.1%, and 22.2%, respectively. While UHCT detected small stones efficiently, in cases of more than one or two opaque calyceal RFs greater than 4 mm, it did not show a statistically valuable increase in the diagnosis compared with KUB and linear tomography. In addition to higher sensitivity, UHCT reduces the total cost required to render patients stone free by reducing the need for second-look flexible nephroscopy in every patient [56].

The ultimate time to perform post-PCNL UHCT is debatable. The end of the first month after surgery is regarded as the optimal timing, taking into consideration that earlier imaging may produce false-positive results from inconsequential dust and may detect RFs that pass spontaneously during the immediate postoperative period [57]. Also, imaging at 1 month has advantages over more immediate imaging because RFs may be obscured by nephrostomy tubes and/or ureteral stents. Under these circumstances the use of bone window during UHCT may be needed to differentiate

between a kidney stone (<1600 HU) and the stents/tubes (>1600 HU) [58].

Management

Is there still a role for shock-wave lithotripsy and "sandwich" therapy?

When PCNL is compared with combination therapy, stone-free rates are higher with PCNL (78% vs 66%), PCNL requires fewer total procedures (1.9 vs 3.3), and transfusion rates are similar for the two modalities (18% vs 17%) [43, 59–61]. Combination therapy is being used less frequently as a result of improvements in endoscopic and intracorporeal lithotripsy technology. Multitract PCNL [50], repeat PCNL or second-look nephroscopy [61] through an established tract may prove more efficient for reducing RFs post PCNL.

Second-look flexible nephroscopy

As demonstrated when the natural history of RFs was evaluated, second-look flexible nephroscopy may benefit patients with RFs larger than 2 mm or those with RFs located in the renal pelvis or ureter [42]. The use of second- and third-look flexible nephroscopies resulted in a 97% stone-free rate in a pediatric population [62].

It is likely that some patients may not have RFs or may pass these spontaneously, making second-look flexible nephroscopy an unnecessary and expensive procedure. Aggressive stone clearance during initial PCNL may obviate the need for routine second-look nephroscopy [63]. Furthermore, careful intraoperative evaluation of stone-free status may lead to avoidance of unnecessary second-look flexible nephroscopy. The intraoperative determination of stone-free status, made prospectively by the combination of the intraoperative radiologic and endoscopy findings, led to negative predictive values of 100%, 88%, and 73% at postoperative CT fragment detection thresholds of 4 mm, 2 mm, and 0 mm, respectively [64]. Nephrostomy tubes were avoided in 44.5% of the patients. Finally, postoperative imaging may reduce the need for second-look flexible nephroscopy by reliably identifying patients without residual stones. An unnecessary flexible nephroscopy would have been avoided by positive UHCT findings in 20% of patients, resulting in significant cost savings of US$109 687 per 100 patients [56].

Ureterorenoscopy

Flexible URS can be considered for the management of patients with post-PCNL RFs [65–67]. Initial clinical experience with digital flexible URS revealed remarkable improvement in image quality as well as zoom capability; however, relevant comparative studies are surprisingly scant and are warranted.

Combined PCNL and flexible URS can effectively increase stone-free rates without increasing morbidity [68–70]. In order to treat RFs after PCNL for a staghorn stone, Undre *et al.* described a technique of synchronous percutaneous nephroscopy and retrograde flexible URS [71]. Two surgeons worked in parallel, one to fragment and relocate the RFs to the pelvis and the other to retrieve them from the mature nephrostomy tract.

Interestingly, a rigid ureteroscope can be used to remove post-PNL RFs. Goel *et al.* described a simple technique of RF removal in patients who underwent PCNL and had a nephrostomy tube *in situ* [72]: under local anesthesia and sedation, a rigid 8.5F ureteroscope was introduced through the nephrostomy tube and the RFs were retrieved. However, this technique is indicated in patients who have RFs of less than 5 mm and located in the same calyx or pelvis as the tip of the nephrostomy tube.

Medical treatment and percutaneous chemolysis

There is some evidence suggesting that medical management, including potassium citrate for hypocitraturia, renal tubular acidosis, chronic diarrhea syndromes, and gouty diathesis; thiazide diuretics for hypercalciuria; and allopurinol for hyperuricosuria, can control active stone formation in patients with RFs after PCNL [73]. Patients on medical therapy exhibited a lower median stone-free rate (0.02 vs 1.00 stones/patient/year) and a higher remission rate (77% vs 21%) compared to patients not on medical therapy, supporting the role of medical treatment in inhibiting new stone formation or growth in patients with RFs following PCNL [73].

Antegrade chemolysis also may have a role in treating RFs after PCNL; however, it has the drawback of prolonged hospitalization, side effects, and increased cost. The ideal chemolysis system should consist of dual nephrostomy tubes (inflow and outflow) and an indwelling ureteral catheter to guarantee passage of RFs [3]. Emphasis should be placed on outflow drainage of the irrigant to keep intrapelvic pressures below 25 cmH_2O. Also, it is important to know the composition of the stone to be treated, in order to choose the appropriate irrigant.

Percutaneous chemolysis with "Suby G" solution may dissolve struvite and apatite stones, but is ineffective in cases of whewellite and weddelite stones [74]. Radiolucent uric acid stones can be successfully disintegrated during percutaneous chemolysis with a 0.1 M sodium bicarbonate solution [75]. Potential side effects such as fever are usually managed conservatively without severe sequelae. In cases of struvite stones,

patients should be closely monitored as there is a risk of urosepsis.

Residual stone fragments following ureteroscopy

Natural history

Since its first description over 20 years ago, URS has progressed from an awkward diagnostic procedure with limited visualization to a precise, complex surgical intervention allowing access to the entire collecting system [76].

There is a paucity of studies specifically designed to evaluate the natural history and management of RFs following ureterolithotripsy. One possible explanation could be that with the development of smaller caliber semi-rigid and flexible ureteroscopes, and the introduction of improved instrumentation, including the holmium : YAG laser, URS has evolved into a safer and more efficacious modality for treatment of stones in all locations in the ureter with increasing experience worldwide [76].

The American Urological Association (AUA) and the European Association of Urology (EAU) have published combined guidelines for the treatment of ureteral stones, based on the meta-analysis of data published up to 2007. Table 58.3 shows the RF percentages extracted indirectly from the stone-free rates following URS when applied as a primary or first treatment choice [77]. Table 58.4 shows the same percentages based on the different types of URS applied. It is important to note that the vast majority of patients were rendered stone free in a single procedure [77].

The clinical significance of small stones remaining after URS is unknown. Indirect inferences can be drawn from studies evaluating the expectant management of ureteric calculi. Spontaneous passage of symptomatic single ureteral calculi is size and time dependent [78]. A meta-analysis comprising 2704 patients treated prior to the advent of SWL and URS showed that when comparing passage rates based on stone size, regardless of location in the ureter, stones of less than4 mm and greater than 6 mm had spontaneous passage rates of 38% and 1.2%, respectively [79]. More recent reviews reported that distal ureteral stones of less than 5 mm in diameter passed spontaneously with a rate of 71–100%, whereas stones of 5–10 mm in diameter passed with a rate of 25–46% [77, 80]. There is a roughly linear relationship between stone size and the likelihood of spontaneous passage, with reported passage rates of 87%, 72%, 47%, and 27% for stones measuring 1, 4, 7, and 10 mm, respectively [81]. Spontaneous passage rates are higher for distal ureteral stones (45–71%) compared with middle (22–46%) and proximal ureteral stones (12–22%) [79, 82]. Moreover, stones of less than 2 mm have a 4.8% chance of requiring intervention during surveillance compared to a 50% chance for stones of 4–6 mm [83].

Schatloff *et al*. were the first to evaluate in a prospective trial the natural history of small RFs remaining in the ureter following semi-rigid URS and holmium laser lithotripsy. Sixty patients were randomized to intraoperative RF retrieval or exhaustive lithotripsy and spontaneous RF expulsion. Patients with RFs, although less than 2 mm in diameter, were associated with a higher risk of unplanned medical visits at 30 days of follow-up. The reasons for a medical visit were renal colic and/or spontaneous stone passage. Patients had to be admitted due to renal colic, distal RFs, and fever or unresponsive

Table 58.3 Median percentage of patients with ureteral residual stone fragments when ureteroscopy was applied as a primary or first treatment option (AUA/EAU Ureteral Stones Guideline panel).

Overall population	G/P	%
Distal ureter	59/5952	6
<10 mm	13/1622	3
>10 mm	8/412	7
Mid ureter	30/1024	14
<10 mm	5/80	9
>10 mm	5/73	22
Proximal ureter	46/2242	19
<10 mm	9/243	20
>10 mm	8/230	21

G, number of groups/treatment arms extracted; P, number of patients in those groups.

Table 58.4 Median percentage of patients with ureteral residual stone fragments when different types of ureteroscopy were applied as a primary or first treatment option (AUA/EAU Ureteral Stones Guideline panel).

	All forms (%)	Flexible (%)	Mixed flexible (%)	Rigid (%)
Total ureter				
<10 mm	7	16	13	5
>10 mm	13	–	19	12
Proximal ureter				
Overall	19	11	13	23
<10 mm	20	16	17	23
>10 mm	21	–	19	19
Mid ureter				
Overall	14	12	12	15
<10 mm	9	–	13	8
>10 mm	22	–	40	20
Distal ureter				
Overall	–	–	–	–
<10 mm	7	16	13	5
>10 mm	13	–	19	12

renal colic. In one patient a nephrostomy tube and eventually ancillary URS were needed. Although the study was prone to methodologic drawbacks, it indicates for the first time that complete stone clearance should be the aim of every ureterolithotripsy [84].

Prevention

The creation of RFs is dependent mostly on the surgical technique. With the advent of the holmium laser the size of RFs was reduced significantly compared to ultrasound, pneumatic, pulsed dye laser or electrohydraulic lithotripsy. More fragments remaining after holmium laser lithotripsy are less than 2 mm, and these may not need to be actively extracted [85]. Differences in the holmium laser technique may result in different RF sizes. Careful vaporization may break the stone into minute fragments as opposed to an exhaustive lithotrpisy which may result in the accumulation of tiny stone fragments in the ureteral lumen that resemble a pile of dust. Clinically significant remnants may be easily missed and left untreated under these circumstances [84, 85].

Another technique to decrease RF size is to increase the laser frequency and shoot the stone in a noncontact fashion, creating the so-called popcorn effect [86]. Proximal stone or fragment migration accounts for significant URS failures [87]. It is associated with a shorter laser pulse length, wider fiber diameter, upper ureteral site, and small stone size. Performing lithotripsy at low energy with little irrigation and actively extracting each fragment as soon as it breaks from the stone may prevent stone migration [84]. Stone retropulsion can also be prevented by using a ureteral occlusion device, such as the Stone Cone® and NTrap®, or stone retrieval baskets such as the Escape™ [88, 89].

Traxer *et al*. have described various techniques of how to avoid accumulation of stone fragments in the lower calyx during flexible URS. Repositioning the stone to another calyx or pelvis, lower calyceal occlusion by autologous blood clot and flank position may also aid in retrograde calyceal stone treatment [90–93].

The impact of ureteral stenting on RF clearance following URS has not been evaluated. However, in a recent meta-analysis of all randomized controlled trials examining ureteral stent placement after URS, no difference in the outcome between patients with and patients without a stent was revealed [94]. There was a slightly lower absolute risk of complications associated with the placement of a ureteral stent after URS. Results from a matched-paired analysis have shown that ureteric stents may compromise stone clearance after SWL for ureteric stones [95]. Whether the same effect could be inferred to URS is unknown. Nevertheless, there are specific groups of patients, like those undergoing bilateral URS, those with urinary tract infections, and pregnant women, who are likely to benefit from stenting [96].

Diagnosis

Studies regarding follow-up after URS are controversial [97–101]. Routine imaging for follow-up has recently been questioned because of the low complication and high success rates of URS stone removal. Additional parameters against routine follow-up are the low percentage of patients suffering symptoms postoperatively, the high association of the presence of symptoms with the existence of residual stones leading to early diagnosis, and the low incidence of silent obstruction following URS. However, the latter is often associated with remaining stone fragments and may cause severe renal deterioration. In addition, there is some evidence that the majority of asymptomatic ureteral stones will pass spontaneously within 4 weeks from diagnosis. With further observation, symptoms and complications may appear in patients [79, 102]. In view of this evidence, most urologists advocate routine follow-up for RFs after URS [101].

The majority of the studies that report on the efficacy of URS use KUB plain radiography, ultrasonography, and/or intravenous urography. With these modalities URS stone-free rates for both renal and ureteral stones have been reported to be 77–81% [103, 104] and 91–100%, respectively [105–108].

Stone-free rates are significantly lower when CT scan is used for follow-up. These rates ranged from 50% to 54% in three studies evaluating the result of URS for lower pole stones of less than 1 cm or for renal and proximal ureteral stones [90, 109, 110]. Overall stone clearance rates increased to 62.8% and 84.1% when the threshold for ureteric success was lowered to allow stone fragments of 2 mm or less and 4 mm or less, respectively [110]. Stone-free rates are significantly higher for ureteral stones (80%) than renal stones (34.8%). Renal units with multiple stones are less likely to be rendered stone free (36.7%) than those with single stones (61%) [110].

Management

Although every possible effort should be made to retrieve stone fragments during URS to avoid future unplanned medical visits [84], it is not clear whether all fragments recognized postoperatively should be actively treated. Similar to post-SWL fragments, RFs larger than 4–5 mm after URS need to be treated with a secondary URS or SWL when located in the pelvis or calyces.

There is a paucity of studies on treatment for smaller RFs post URS. A recent study randomized, patients to active retrieval versus spontaneous passage of stones

during holmium laser ureterolithotripsy [84]. In the latter group, the stone was completely turned into dust or fragments of less than 2 mm, which were left *in situ*. There was no statistical difference in hospitalization, need for pain analgesia, time to complete recovery, stone-free rate, and need for ancillary procedures at 30 days of follow-up. For stones sized between 2 and 5 mm, the existing evidence for spontaneous ureteric stone passage and the fate of RFs following SWL indicate that treatment should be individualized [77–83].

Conclusions

The definition of "clinically significant residual stone fragment" is based on arbitrarily set criteria. There is some evidence indicating that as the burden and number of clinically insignificant RFs increases, the risk of becoming clinically significant also increases. Moreover, as the duration of follow-up increases, the rate of complications and the need for intervention due to symptomatic episodes also increase. SWL retreatment, with or without patient inversion, of completely fragmented but persistent stone debris appears to be justified to render the kidney stone free following primary SWL. Medical therapy can control active stone formation, reduce growth or agglomeration, and increase the clearance rate of RFs after SWL.

RFs following PCNL can occur in up to 8% of patients. When left untreated, approximately half of these patients will experience a stone-related event, for which more than half will require a secondary surgical intervention. For these reasons, urologists should take all measures to prevent their creation, carefully identify their existence postoperatively, and actively deal with them by a second-look flexible nephroscopy and/or flexible URS. Medical therapy may control active stone formation and growth in patients with RFs after PCNL.

Patients with RFs following URS are associated with a higher risk of unplanned medical visits and a tendency towards higher rates of rehospitalization, residual stones, and the need for ancillary procedures. Appropriate stone disintegration and removal of all stone fragments should be the aim of every ureterolithotripsy. Using technology properly to avoid the creation of large RFs and to prevent stone migration may eventually decrease the RF rates. There is a paucity of studies on treatment for post-URS RFs. Evidence derived from the spontaneous ureteric stone passage and from the fate of RFs following SWL indicates that treatment should be individualized.

CHAPTER 59

Management of Renal Colic and Triage in the Emergency Room

Marius Cloete Conradie

Department of Urology, Nelson R. Mandela School of Medicine, Greys Hospital, Pietermaritzburg, South Africa

Introduction

Acute renal colic is probably the most painful event a person can endure. Renal colic affects approximately 1.2 million people each year and accounts for approximately 1% of all hospital admissions. Most active emergency rooms (ERs) treat an average of at least one patient with acute renal colic every day, depending on the size of the hospital [1]. Renal colic is often the supposed diagnosis made in the ER in patients presenting with acute onset of flank or loin pain. Often, multiple investigations are done before the diagnosis is confirmed. Frequently this causes a delay in appropriate management. It is up to the attending physician or urologist not only to make the prompt diagnosis but also to initiate effective pain control and identify potentially complicated renal colic.

Classic presentation of renal colic: symptoms and signs

Patients with acute renal colic classically present with a sudden onset of severe pain originating in the flank. The initial presentation typically lasts 3–18h. The progression of pain has been described as having three clinical phases. The typical attack starts slowly and insidiously. The pain is usually steady, increasingly severe, and continuous. The pain typically waxes and wanes in severity, and develops in waves or paroxysms that are related to movement of the stone in the ureter and associated ureteral spasm. Paroxysms of severe pain usually last 20–60min. Pain is thought to occur primarily from urinary obstruction with distention of the renal capsule. The pain reaches its maximum 1–2h after the start. In the constant phase, the period of sustained maximal pain, the pain tends to remain constant until it is either treated or allowed to improve spontaneously. Most patients arrive in the ER during this phase of the attack. In the final phase of renal colic, relief can occur spontaneously at any time after the initial onset and most commonly lasts 1.5–3h.

The pain may localize at different sites of the abdomen depending on the exact position of the calculus in the urinary tract. Stones commonly become impacted in the urinary tract in a calyx, at the ureteropelvic junction (UPJ), at the pelvic brim where the ureter begins to arch over the iliac vessels, at the broad ligament in females, and at the ureterovesical junction, which is the most common site of impaction. Pain from upper ureteral calculi tends to radiate to the flank and lumbar areas. Mid-ureteral calculi cause pain that radiates anteriorly and caudally. Distal ureteral calculi cause pain that tends to radiate into the groin or testicle in the male or labia majora in the female. If a calculus is lodged in the distal intramural part of the ureter, symptoms may mimic detrusor overactivity or cystitis. These symptoms include suprapubic pain, urinary frequency, urgency, dysuria, or pain at the tip of the penis in men.

On examination of the abdomen, the pain localizes to the costovertebral angle. The remaining examination findings are often unremarkable. The characteristic difference between patients with renal colic and those with an acute abdomen lies in the restlessness of patients

Smith's Textbook of Endourology, Third Edition. Edited by Arthur D. Smith, Gopal H. Badlani, Glenn M. Preminger, Louis R. Kavoussi.

with renal colic. Patients with an acute abdomen of surgical origin usually lie as still as possible. Rebound tenderness will be present in an abdomen with peritonitis. The pain is generally diffuse in an acute abdomen as opposed to renal colic where the patient can often point to the site of maximum tenderness, which is likely to be the site of the ureteral obstruction.

Hematuria is often associated with renal colic. However, 15% of all patients with urinary calculi do not have hematuria [2]. Therefore, the lack of hematuria does not exclude the possibility of acute renal colic. Other clinical signs that may be encountered are fever, chills, nausea, vomiting, and tachycardia. The presence of pyuria, fever, leukocytosis, or bacteriuria suggests the possibility of a urinary infection and the potential for an infected obstructed kidney. This is a potentially life-threatening situation and should be treated as a surgical emergency.

Mechanism of renal colic

Renal colic is the consequence of the acute dilation of the urinary tract proximal to an obstruction along with smooth muscle spasm at the site of the obstruction. High intrarenal pressure promotes local synthesis and release of prostaglandin E2 with subsequent vasodilation of the afferent arterioles, which promotes diuresis and a further rise in renal–pelvic pressure, potentially exacerbating the patient's pain. In addition, ureteral smooth muscle spasm is directly stimulated by prostaglandin E2 [3]. Most of the pain receptors of the upper urinary tract responsible for the perception of renal colic are located submucosally in the renal pelvis, calyces, renal capsule, and upper ureter. Acute distention seems to be most important in the development of the pain of acute renal colic. Muscle spasm, increased proximal peristalsis, and local inflammation at the site of obstruction may contribute to the development of pain through chemoreceptor activation and stretching of submucosal free nerve endings. Renal colic pain rarely, if ever, occurs without obstruction.

Autoregulatory process associated with obstruction

The initial renal response to acute unilateral ureteral obstruction is the release of prostaglandins, especially E2, resulting in vasodilatation of the afferent arterioles and worsening of ureteral smooth muscle spasm. Subsequently, the dilation of the afferent arterioles results in an increase in renal blood flow and glomerular filtration rate [4]. As a consequence, more urine is produced, and the renal pelvis and ureter dilate further. Distention of the renal pelvis initially stimulates ureteral hyperperistalsis. Peak hydrostatic renal pelvis pressure is attained within 2–5 h after a complete obstruction. The initial phase of obstruction lasts approximately 1.5 h and is followed by vasoconstriction of the efferent arterioles with a resultant decrease in renal blood flow. Eventually, the afferent arterioles constrict and ureteral pressures fall [4]. By this time, intraureteral pressures have returned to normal, but the proximal ureteral dilation remains and ureteral peristalsis is minimal. The interstitial edema of the ipsilateral kidney enhances fluid reabsorption, which helps to increase the renal lymphatic drainage to establish a new, relatively stable, equilibrium. At the same time, renal blood flow increases in the contralateral kidney as renal function decreases in the obstructed kidney. The return of renal function after a period of complete unilateral ureteral obstruction is an important clinical concern for the urologist. The renal function recovery rate after 1 week of ureteral obstruction is 100%, but after 4 weeks only a 30% recovery can be expected [5]. If only a partial obstruction is present, the same changes occur, but to a lesser degree.

Diagnosis

The diagnosis of renal colic is often made based on clinical symptoms alone, although confirmatory tests are usually performed. Additional tests are useful not only to confirm the diagnosis but also to facilitate in the decision-making process on further treatment. Before a decision on treatment can be made, a urologist must know the size, shape, orientation, radiolucency, and location of the stone. Other factors that may influence further treatment are kidney function and the presence of infection, as well as all other clinical information and comorbid conditions the patient may have.

Laboratory investigations

Urinalysis

Patient history, physical examination, and urinalysis alone cannot help confirm or exclude urolithiasis with sufficient accuracy. In particular, hematuria testing has a sensitivity of 81–84% and a specificity and negative predictive value of 48% and 65%, respectively [6, 7].

In addition to the presence of blood in the urine, the presence or absence of leukocytes, crystals, and bacteria, and the urinary pH should be documented. A urinary tract infection should be suspected if the number of white blood cells (WBCs) in the urine is greater than 10 per high-power field. Determining urinary pH may be helpful in planning treatment. With a pH lower than 6.0, a uric acid stone should be considered. The observation of cystine, uric acid, struvite, or calcium oxalate crystals in the urine may be an indication of the type of calculus ultimately found.

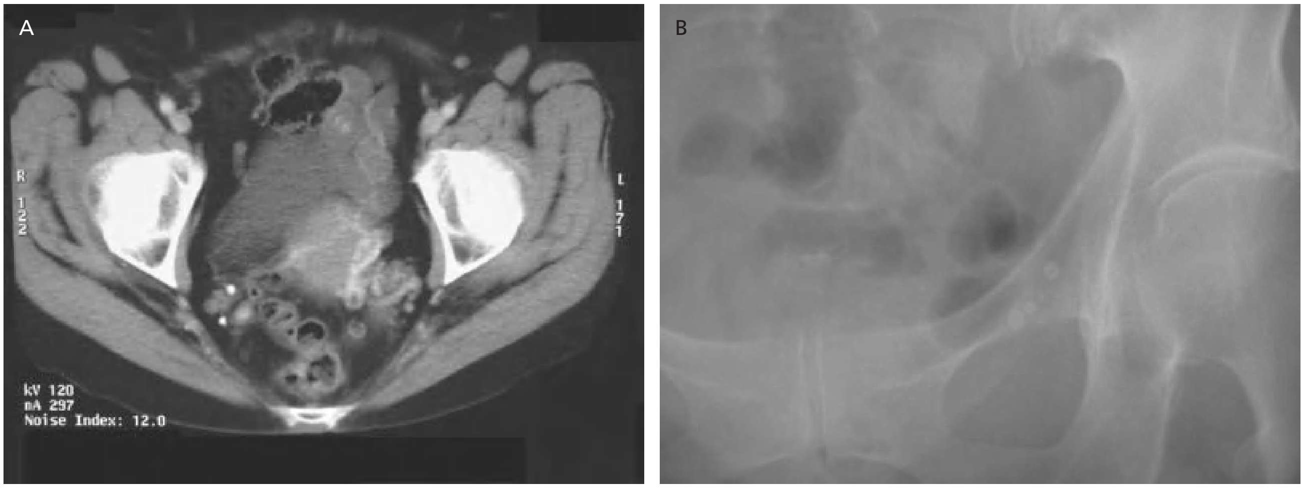

Figure 59.1 (A) Distinguishing renal calculi from phleboliths in the pelvis can be intricate. This axial noncontrast CT demonstrates two phleboliths in the pelvis. One demonstrates the comet-tail sign, which is a soft tissue attenuation leading to the phlebolith and represents the vein in which it is located. (B) On a KUB radiograph, a phlebolith classically demonstrates a central lucency whereas ureteral calculi do not.

Hematologic tests

While mild leukocytosis often accompanies a renal colic attack, a high index of suspicion for a possible infection should accompany any serum WBC count of 15 000/µL or higher in a patient presenting with an apparent acute kidney stone attack, even if afebrile. Urea, creatinine, and electrolyte testing may be helpful in identifying patients with renal function impairment as well as in giving some information on the hydration status of the patient, which may determine their further management.

Imaging studies

Plain abdominal radiograph

The historical cornerstone of the evaluation of renal colic was a radiograph of the kidneys, ureters, and bladder (KUB). Not all urinary calculi will be visible on the KUB radiograph because of their small size, calculus radiolucency, or overlying bowel gas. Typically, 90% of calculi are radio-opaque. However, many calcifications that can be observed on the KUB radiograph are not calculi, but phleboliths, vascular calcifications, calcified lymph nodes, or bowel contents. Typically the differentiation between a phlebolith and a urinary calculus becomes easier when the KUB radiograph demonstrates a lucent center, identifying the calcification as a phlebolith. However, this central lucency is not observed as often on computed tomography (CT) scans. The KUB radiograph is also quite accurate for helping determine the size and shape of a visible radio-opaque calculus. It uses the same orientation and anatomic presentation that is observed on fluoroscopy images during endoscopic ureteral surgery. Also, the progress of the stone can be easily monitored with a follow-up radiograph. For these reasons, many urologists recommend a KUB in addition to a CT scan in the work-up of renal colic (Figure 59.1).

Renal ultrasound

Renal ultrasound is most useful in diagnosing relatively large calculi within the renal pelvis or kidney. However, it is less useful than other modalities for detecting ureteral calculi. One benefit is that it can easily diagnose any significant hydronephrosis. Ultrasound can also be used to diagnose other pathologic conditions such as abdominal aortic aneurysm or cholelithiasis, which can sometimes be mistaken for acute renal colic. Combining a renal ultrasound with a KUB radiograph can be adopted as a reasonable alternative when a CT scan cannot be performed.

Intravenous urogram

Intravenous urography (IVU) has been the imaging modality of choice for investigating acute renal colic since Osborne *et al.* first described it in 1923 [8]. It provides detailed information about the anatomy of the renal collecting system and ureters, offers some information about renal function and the degree of obstruction, and is good for the planning of calculus surgery (Figure 59.2). When a patient has multiple pelvic calcifications, identifying the actual stone is simple with an IVU and it can also show nonopaque calculi as filling defects.

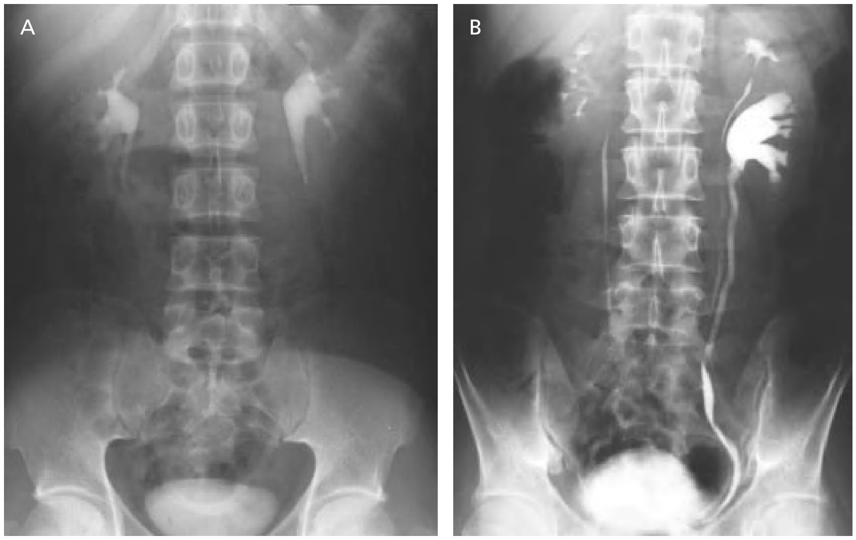

Figure 59.2 (A) An intravenous urogram (IVU) obtained in a patient with renal colic demonstrates a calculus of less than 6 mm, normal anatomy, and no signs of obstruction, which makes for the ideal candidate for medical expulsive therapy. (B) IVU image demonstrates a calculus of greater than 6 mm at the ureteropelvic junction in the lower moiety of a kidney with complete ureteral duplication. This represents a clear indication for surgical intervention.

There are, however, limitations: adequate bowel preparation is necessary for good quality studies, and there is a risk of contrast-related allergic and anaphylactic reactions (10% and 1% of patients, respectively) [9]. Also, in patients with renal failure and diabetes mellitus, the risk of contrast-induced nephrotoxicity is 25% [10]. A serum creatinine level of more than 2 mg/mL is a relative contraindication to the use of intravenous contrast. Furthermore, there may be a need for delayed films if there is high-grade obstruction, which can lead to delays in diagnosis and treatment.

The classic finding of acute ureteral obstruction is a persistent nephrogram, caused by an increase in the intrarenal concentration of the contrast. Even without observing any specific calculus, the presence of a persistent nephrogram in one kidney with prompt contrast excretion by the contralateral kidney is highly suggestive of ureteral obstruction secondary to a calculus. There may also be columnization on the delayed films. Extravasation of contrast around the collecting system may be a sign of a ruptured fornix, while pyelolymphatic backflow indicates that contrast has entered into the renal lymphatic drainage system. Both are considered signs of a more severe ureteric obstruction.

Computed tomography scan

The use of a noncontrast helical CT (NCCT) scan to assess patients with acute flank pain was first reported in 1995 by Smith *et al*. [11]. Recent studies have shown that NCCT is more accurate and reliable than IVU in making a diagnosis in patients presenting with acute flank pain. NCCT has both sensitivity and specificity of 94–100% compared with 60–94% for IVU, partly because NCCT clearly demonstrates both radio-opaque and radiolucent stones, as well as detecting alternative causes for a patient's symptoms [12, 13]. Unrelated pathology may be detected by NCCT in 28% of patients [14]. Moreover, NCCT does not require special preparation or intravenous contrast, thus avoiding the risk of contrast-associated reactions and allowing imaging studies to be completed in a few seconds, which improves image quality by reducing respiratory motion and artifact [15, 16]. For these reasons, NCCT has displaced IVU to become the investigation of choice for acute flank pain in many institutions across North America, Europe, and Australasia [13, 17, 18].

Very narrow cuts are taken through the kidneys and bladder areas, where symptomatic calculi are most likely to be encountered (Figure 59.3). A KUB radiograph is sometimes automatically included in a renal colic study, as mentioned earlier.

Katz *et al*. found that CT scan estimates of stone size to be similar to those determined by plain film radiography [19]. Both the estimated mean stone diameter and the length were similar on CT and KUB. The limitation of this method is that if CT collimation is too large relative to the stone, the entire stone may not be scanned, leading to underestimation of stone length. This inaccuracy can be best compensated for by making sure that slices are small in relation to stone size. Therefore, 5-mm collimation is preferred to 10-mm collimation. In addition to verifying similarity of stone size estimates by CT and KUB, Katz *et al.* also found that the prediction of

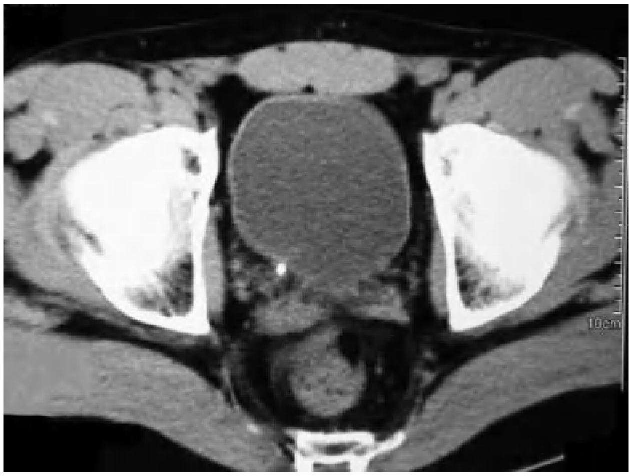

Figure 59.3 Classic example of a calculus of less than 6 mm at the ureterovesical junction. Medical expulsive therapy would be an appropriate course of action.

spontaneous stone passage was similar using the two imaging modalities. It is widely believed that transverse stone dimension is more important than length in predicting the likelihood of spontaneous passage. Interestingly, the study demonstrated the measured anteroposterior stone diameter on CT to be wider in many cases than the measured transverse diameter on CT and plain film. This result could be explained by orthogonal imaging in curved portions of the ureter, where larger anteroposterior diameters were found irrespective of stone location. At any given point along the CT scan, the ureter is either ascending or descending; therefore, an anteroposterior cut would slice tangentially, and cause a wider anteroposterior than transverse diameter.

Phleboliths are often confused with ureteral calculi. On a KUB radiograph, the characteristic lucent center of a phlebolith is often visible, but is not present in a true calculus. Unfortunately, as mentioned above, CT scans usually fail to reveal this central lucency. The "rim sign," originally reported by Smith *et al.* in 1995, is described as a rim or halo of soft tissue, visible on CT scans, that completely surrounds ureteral calculi [11]. This effect is enhanced by the local inflammation in the ureteral wall with subsequent edema at the site of the calculus. The rim sign is generally incomplete with phleboliths. The rim sign is more likely to be present in small stones up to 5 mm in diameter.

Calculi, including relatively radiolucent uric acid calculi, and cystine and matrix stones are easily identifiable on CT scan. While they do not contain calcium, they are still much denser than the surrounding soft tissue. The only exception is indinavir calculi, which are not visible on CT scans. These patients require an IVU that will demonstrate a filling defect.

Currently, CT scans can be used to estimate the relative density of the calculus and composition to some extent. The mean peak Hounsfield reading of uric acid calculi and calcium oxalate calculi are around 344 ± 152 HU and 652 ± 490 HU, respectively [20].

Secondary signs of obstruction may be visible on CT scans. In some cases, if the stone passed shortly before the study, these signs may be the only evidence that the patient had a stone. These secondary signs include ureteral dilation with hydronephrosis and renal enlargement with streaking of the perinephric fatty tissue [2]. Although NCCT is unable to provide direct information on function and drainage, the degree of obstruction can be assessed by secondary signs, such as the severity of hydronephrosis and ureteral dilation and the presence of perinephric fluid, indicating forniceal rupture. Smith *et al*. found a high correlation between secondary signs of obstruction and the presence of a ureteral calculus. In particular, the combination of collecting system dilation and perinephric stranding had a positive predictive value of 98%, while the absence of both of these secondary signs had a negative predictive value of 91% [21].

The biggest advantage of a CT scan over an IVU lies in its ability to diagnose other underlying pathology mistaken for renal colic, such as aortic aneurysms, pancreatitis, appendicitis, ovarian problems, and bowel disorders.

Disadvantages of a CT scan include difficulties in identifying a stone if the patient exhibits limited hydronephrosis with additional pelvic calcifications and the little information it gives on the renal function. Stone location can be described in anatomic terms, but the scan lacks the surgical orientation that most urologists prefer. Spiral CT scans can, however, allow for anatomic three-dimensional image reconstruction, which may be useful in the evaluation and pretreatment planning (Figure 59.4).

It is recommended to add a KUB radiograph when a renal colic CT scan study is performed for acute flank pain, especially when the CT scan findings are positive for urolithiasis. The KUB radiograph not only provides more precise information about the size and shape of a stone, but it also quickly reveals whether stones are radio-opaque or radiolucent. Follow-up evaluations are easier because only a repeat KUB radiograph is needed for comparison.

Differential diagnoses of renal colic

Alternative urologic pathology

Pyelonephritis

Pyelonephritis is a common cause of flank pain, but the discomfort is usually described as a relatively mild dull

Figure 59.4 3D reconstruction of a noncontrast CT of a patient with a single kidney with a calculus impacted at the pelvic brim. This imaging option can be a valuable adjunct in high-risk patients in choosing the most appropriate treatment option as well as pretreatment planning.

ache rather than typical renal colic pain. Fever, chills, nausea, and vomiting are often associated symptoms. Flank and costovertebral angle tenderness are also present, but more severe than with renal colic.

Renal abscesses

Renal abscesses tend to cause pain similar to pyelonephritis rather than renal colic. Sometimes, a flank mass may be palpable. Urinalysis often demonstrates a urinary infection, but can be normal in some cases. Fever and chills are common. It is usually associated with patients who are immune compromised.

Kidney tumors

Kidney tumors may cause flank pain either from renal capsular stretching or by mechanical compression of large tumors. Primary tumor extension into the renal pelvis can cause urinary obstruction, although this is usually a slow process during which patients are often asymptomatic.

Ureteropelvic junction obstruction

UPJ obstruction is one of the more common causes of renal pain. The pain is similar to an acute ureteral obstruction and usually follows the intake of large amounts of fluid, which causes diuresis resulting in renal pelvic distention and colic. The pain is not as severe as renal colic and is recurrent in nature.

Obstructive uropathy due to other causes

Other obstructive causes include:
- Blood clots;
- Renal papillary necrosis;
- Ureteral strictures;
- Renal cysts;
- Polycystic kidney disease;
- Pyelocalyceal diverticulum.

Vascular pathology

Abdominal aortic aneurysms

Patients with an abdominal aortic aneurysm may present with symptoms of flank pain that mimic renal colic. Symptoms are generated from either a leaking or ruptured aneurysm. Large aneurysms may lie in close approximation to the ureter and cause hematuria from local ureteral inflammation. Abdominal aortic aneurysms are best diagnosed with ultrasound or a CT scan. CT scanning is particularly useful in cases of suspected renal colic in patients older than 50 years, who are at risk for an aortic aneurysm.

Gastrointestinal tract pathology

Causes include Crohn's disease, diverticulitis, appendicitis, cholecystitis, and pancreatitis.

Gynecologic pathology

Causes include ectopic or tubal pregnancy, endometriosis, ovarian cyst, and pelvic inflammatory disease

Medical and surgical treatment (Figure 59.5)

The management of acute renal colic is a problem commonly encountered by both urologists and emergency medicine physicians. One aspect of the medical treatment is the management of acute renal colic pain, a condition that demands rapid and effective analgesia. Currently, nonsteroidal anti-inflammatory drugs (NSAIDs) and opioids are the best agents for acute renal colic, overshadowing other drugs such as antimuscarinics (i.e. hyoscine butylbromide) [22].

In addition to controlling the pain associated with obstructing calculi, drug therapy that promotes the expulsion of stones is an evolving aspect of medical therapy.

Observation with analgesia is most appropriate for patients without infection whose pain can be well-controlled with oral medications. Key factors contributing to stone retention include edema, ureteral spasm, and infection, all of which are potential pharmacologic

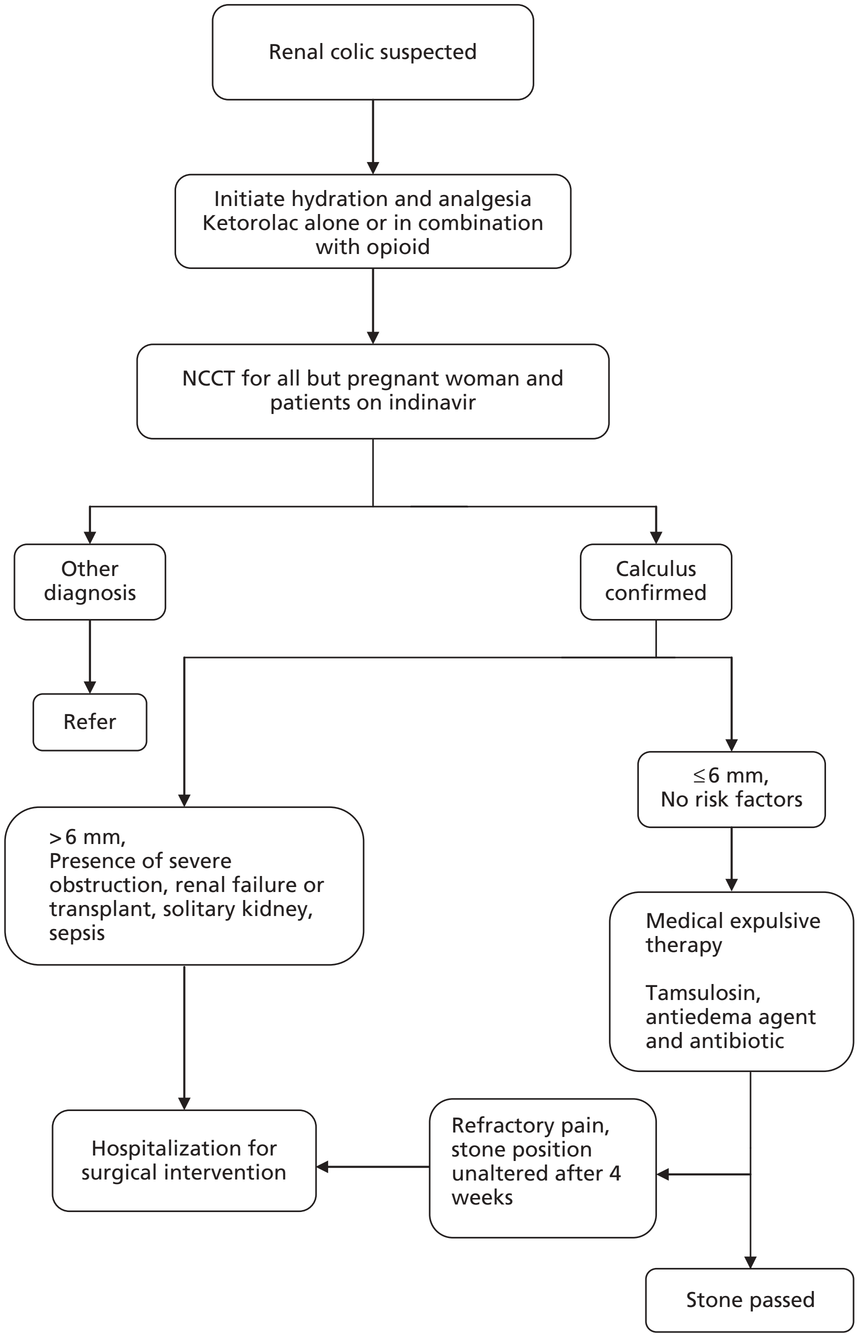

Figure 59.5 Algorithm depicting the course of evaluation, triage, and further management of a patient with suspected renal colic. NCCT, noncontrast CT.

targets. However, in cases of persistence, ureteral obstruction, or pain, other minimally invasive interventions are preferred [23].

Triage

The majority of ERs in the USA (87.4%) do not have guidelines regarding the treatment of patients who present with renal colic [1]. Having well-designed guidelines in the ER will not only facilitate and expedite diagnosis and enable appropriate treatment, but will also significantly decrease patient morbidity and channel patients with life-threatening conditions to the appropriate departments without delay. Such guidelines should help acquire the most suitable imaging modalities, decide which patients should be hospitalized or referred to other departments, and facilitate in the triage and decision-making on conservative versus surgical therapy.

Predicting spontaneous stone passage

Setting patient expectations with regard to the likelihood of spontaneous stone passage and the time to stone passage is critical to help guide the patient to make an informed decision between conservative management and surgical intervention. The management of patients with ureteral calculi relies on estimated stone size and the stone's potential for spontaneous passage. Several factors influence the likelihood of spontaneous stone passage, such as location and history of spontaneous expulsion. Indeed, with accurate information, more patients might select early intervention as opposed to expectant observation. In general, smaller calculi are more likely to pass spontaneously, but stone passage also depends on the specific anatomy of the upper urinary tract. Any anatomic abnormality could make the passing of even a small stone impossible.

Spontaneous passage of urinary calculi of less than 5 mm in diameter may occur in most patients, although the calculus may take 40 days or more to pass [24]. Prospective clinical trials have stratified the spontaneous stone passage rate and time to stone passage. Stones of 4 mm and smaller have a 94% chance of spontaneous passage, whereas stones of 4–6 mm in size will pass spontaneously 50% of the time. Average time to stone passage was 1 week for a stone of less than 2 mm, 2 weeks for a stone of 2–4 mm, and 3 weeks for a stone of 4–6 mm. Calculi of greater than 6 mm are unlikely to pass spontaneously [25–28].

Excluding complications related to stone disease, such as severe hydronephrosis, renal insufficiency, intractable pain, and infection, that mandate a more aggressive approach (ureteral stent, nephrostomy, retrograde intrarenal surgery, extracorporeal shock-wave lithotripsy), drug therapy is useful in the management of urolithiasis and represents an important adjunct to conservative therapy.

With regard to cost, observation represents the most cost-effective approach to ureteral calculi, but it remains unsatisfactory for recurrent stone formers, in whom the high rate of recurrence precludes a conservative approach [29]. A cost-effectiveness model revealed that a conservative approach to ureteral stones is associated with lower cost than any invasive procedures only if it is followed by stone expulsion [30].

It is suggested that a conservative approach to larger ureteral stones should not be extended for longer than 2 weeks in order to avoid renal function impairment, urosepsis, and intractable pain [31]. Many urologists have adopted the conservative treatment plan of 4 weeks proposed by Hubner *et al*. [28]. This is safe if the stone is 6 mm or smaller in the absence of severe hydronephrosis.

Hospitalization

The decision to hospitalize a patient with a stone is usually made based on clinical grounds rather than on any specific finding on a radiograph. Watchful waiting for spontaneous stone passage is certainly the least invasive management option; however, several signs and symptoms may prohibit such a course of action. Fever, chills, or other sign of infection are the most urgent scenarios prohibiting watchful waiting. Evidence of renal insufficiency or frank anuria similarly necessitates urgent intervention. Poorly controlled renal colic pain and vomiting are more subjective indications. Other than extreme cases necessitating inpatient management, clinical scenarios that may warrant acute intervention include inability to perform routine activities safely and reliably, upcoming travel plans, job restrictions, etc. [32]. Patients with obstructing ureteric stones of greater than 6 mm are seldom likely to pass their stone spontaneously, and early admission for procedural therapy may be prudent [2]. Most patients with acute renal colic can be treated on an ambulatory basis. Hospitalization for an acute renal colic attack rarely lasts for longer than 24 h, after which the patient can go home.

Surgical intervention

The presence of urosepsis in a patient with an obstruction from stone disease is a true surgical emergency. This condition requires hospital admission with intravenous fluids, antibiotics, and most importantly, early drainage of the affected kidney using either retrograde placed double-J stents or percutaneous nephrostomy.

Retrograde endoscopy should be reserved for relatively mild cases that are medically stable. Double-J stents virtually guarantee drainage of urine from the kidney and bypass the obstruction. This relieves patients of their renal colic pain even if the actual stone remains.

In patients with pyonephrosis in association with an obstructing calculus, retrograde endourologic procedures, such as retrograde pyelograms and double-J stent placement, may worsen the infection by pushing infected urinary material into the obstructed kidney and may exacerbate the systemic sepsis. These situations clearly indicate the need for a percutaneous nephrostomy, especially in patients who are hemodynamically unstable. Later, when the infection is under control and the patient is no longer septic, a more definitive procedure can be performed to remove or fragment the obstructing stone.

Approximately 10–20% of all kidney stones may cause the patient enough problems to require surgical removal. If there is no evidence of movement or passage of a ureteral stone that has been treated conservatively for 3–4 weeks or if pain is intractable, surgical intervention

is warranted. Other conditions that may require a more expedited approach are the presence of unusually large stones, high-risk medical conditions, uncontrollable pain, renal failure, solitary kidneys, renal transplants, and pregnancy.

Hydration

Initial treatment of a renal colic patient in the ER starts with obtaining intravenous access to allow fluid, analgesic, and antiemetic medications to be administered. Some patients may be dehydrated from nausea and vomiting. Some believe hydration may increase the speed of passage of a stone through the urinary tract. Traditionally, patients were aggressively hydrated intravenously or were told to increase their oral hydration in order to promote stone passage [33]. This practice stems from the thought that the stone might pass spontaneously if forced hydration is utilized. Using hydration as a therapy to assist stone passage remains controversial.

Some urologists worry that the extra fluid only increases the hydrostatic fluid pressure inside the blocked renal unit, exacerbating the pain. In addition to this, diuresis may be detrimental to the ipsilateral renal unit by potentially causing forniceal rupture [34, 35]. Therefore, fluid restriction may be more advantageous to the patient.

Maintenance intravenous fluids are as efficacious as forced hydration with regard to patient pain perception and narcotic use. Moreover, it appears the state of hydration has little impact on stone passage [36].

Intravenous hydration during an episode of renal colic is necessary in patients who are unable to tolerate liquids by mouth. It is therefore recommended that patients who have been vomiting or have laboratory values suggesting dehydration receive appropriate replacement fluids plus their normal maintenance requirements.

Pain relief

The two principal classes of drugs used for analgesia in renal colic are NSAIDs and opioids. The combination of these drugs is currently the preferred treatment of renal colic at most emergency departments.

Narcotics and opioids

The mainstay of medical therapy for patients with acute renal colic is parenteral narcotic analgesics. These medications work primarily on the central nervous system (CNS) to reduce the perception of pain. When considering a medication and dosage range, it must be remembered that acute renal colic is probably the most painful episode to affect humans. Morphine, meperidine, and tramadol are the most commonly used drugs.

Morphine is the principal opium alkaloid product. As a potent narcotic analgesic, morphine sulfate controls severe pain primarily through a CNS mechanism. Adverse effects include respiratory depression, drowsiness, nausea, and vomiting. The usual dose of morphine sulfate is 10 mg/70 kg of body weight intramuscularly every 4 h. For more rapid results, morphine sulfate can be administered intravenously in doses of 4–10 mg, but it must be administered slowly to avoid excessive adverse effects and respiratory depression.

Similar to morphine sulfate, meperidine is a potent parenteral narcotic analgesic. Doses of 1 mg/kg should be adequate to bring relief to a patient with renal colic. Meperidine offers a slightly more rapid onset of action and slightly shorter duration of analgesic activity than morphine sulfate. The dosage range is usually 1 mg/kg intramuscularly every 4 h. This dosage is reduced by at least 50% when administered intravenously. The actual effective dosage varies according to the source of the pain and the individual's tolerance. As with morphine sulfate, intravenous administration should be performed slowly.

Tramadol is a synthetic cyclohexanol derivative used since the late 1970s. It is a centrally-acting analgesic with inhibition of serotonin and norepinephrine reuptake. Fewer side effects are seen with tramadol, although it is less effective for severe pain [37]. Negligible cardiac and respiratory depression has been shown, and reported side effects are minor: mainly nausea and emesis, usually preventable by slow injection of the drug and prophylactic administration of an antiemetic.

For long-lasting pain relief, intravenous opioids titrated to effect are recommended. However, on-demand intravenous titration of drugs is difficult to organize in a busy emergency department, especially if patients have to leave for the medical imaging department. A continuous intravenous tramadol drip, on the other hand, proved to offer superior analgesia and greater patient satisfaction without an increase in reported side effects [37].

Nonsteroidal anti-inflammatory drug therapy

NSAIDs have a direct action on the underlying cause of the pain by inhibiting prostaglandin synthesis, and subsequently reduce vasodilatation with a drop in intrarenal pressure, inhibit ureteral smooth muscle contraction, and reduce urinary tract inflammation [38].

There are various NSAIDs available for either intramuscular or intravenous use. The most common intravenous NSAID used in the USA is ketorolac, which works at the peripheral site of pain production rather

than on the CNS. It has fewer adverse effects and often provides dramatic improvement in pain symptoms. The dosage is an initial 30–60 mg intramuscularly or 30 mg intravenously, followed by 30 mg intravenously or intramuscularly every 6–8 h. Ketorolac has been shown to be as effective in the treatment of renal colic as the narcotic meperidine [39, 40].

In more severe cases, ketorolac can be combined with narcotic analgesia with better analgesic effect than either one administered individually. Once the acute episode has been dealt with, an oral NSAID can be used. Of the various enteral NSAIDs, ketorolac, ibuprofen or the newer oral cyclo-oxygenase-2 inhibitors are equally effective for pain management in outpatients. Chemically, ketorolac and ibuprofen are similar to Aspirin and may increase the prothrombin time when administered with anticoagulants. They should be avoided in patients with peptic ulcer disease, renal failure, or recent gastrointestinal bleeding.

Antidiuretics

Desmopressin (DDAVP), a potent antidiuretic medication that is essentially an antidiuretic hormone, can dramatically reduce the pain of acute renal colic in many patients. It is thought to work by reducing the intraureteral pressure, but it may also have some direct relaxing effect on the ureteral musculature. Whether this therapy significantly affects eventual stone passage is unknown [41].

It is available as a nasal spray (usual dose of 40 μg) and as an intravenous injection (4 μg/mL). Generally, only one dose is administered.

While some of the human studies lack adequate controls and further studies must be conducted, desmopressin therapy currently appears to be a promising alternative to analgesic medications in patients in whom narcotics cannot be used or in whom the pain is unusually resistant to standard medical treatment.

Antiemetics

Because nausea and vomiting frequently accompany acute renal colic, antiemetics often play a role in renal colic therapy. Metoclopramide is a well-known agent in the treatment of renal colic. Its antiemetic effect stems from its dopaminergic receptor blockage in the CNS. The effect after intravenous injection of 10 mg is rapid; within 3 min the patient experiences relief. Other medications commonly used as antiemetics include promethazine and prochlorperazine. Anti-emetics are recommended when patients with renal colic have been vomiting actively or report nausea sufficient to interfere with oral therapy.

Medical expulsive therapy

As discussed above, stone size affects expulsion times, but other factors such as stone shape and edema around the stone may also have an effect. Additionally, the sympathetic nervous system modulates ureteral activity, as demonstrated by the presence of adrenergic receptors in the ureter. Various medications or combinations thereof have been used to facilitate and expedite the passage of ureteral stones. The rationale for the combination of an anti-inflammatory drug (NSAID or steroid) with a smooth muscle relaxant (nifedipine or tamsulosin) is that the former will reduce edema while the latter will inhibit stone-induced ureteral spasm, thus maintaining peristaltic rhythm [30, 42, 43].

However, medical expulsive therapy (MET) should only be used in favorable conditions for spontaneous stone passage. Patients who elect for MET should have well-controlled pain, no clinical evidence of sepsis, and adequate renal functional reserve. Patients should be followed with periodic imaging studies to monitor stone position and to assess for hydronephrosis. Since patient complaints and stone size do not predict future renal function loss and time to permanent renal injury cannot be easily estimated, intervention should be recommended for any patient with persistent obstruction, failure of stone progression, or recurrent colic pain.

Alpha-adrenergic antagonists

The presence of alpha- and beta-adrenergic receptors have been demonstrated in human ureters. α1-Adrenergic receptors, particularly subtype α1d, are present in high density in the lower ureteral segment and may play an important role in lower ureteral physiology [44]. Norepinephrine is the main alpha-agonist and exerts a positive chronotropic and inotropic effect on the ureter. As a result, stimulation of alpha-adrenergic receptors decreases the volume of urine flow through the ureter.

Alpha-adrenergic antagonists are able to inhibit the basal tone and peristaltic frequency, dilating the ureteral lumen and facilitating in stone passage [45]. Several investigators have shown the utility of α1-blockers and their spasmolytic action in the active expulsion from the distal ureter [31, 46]. Tamsulosin may increase the urine bolus, and thus the pressure, above the stone; at the same time, the agent may decrease peristalsis, and thus the intraureteral pressure, below the stone. The net effect is an increased intraureteral pressure gradient around the stone, which ultimately results in a stronger expulsive force [35].

Yilmaz *et al*. evaluated tamsulosin, terazosin, and doxazosin alone compared with watchful waiting and found a significant increase in spontaneous stone

passage with all three alpha-blockers (79%, 78%, 76%, and 53%, respectively) [47]. A recent meta-analysis of 11 randomized clinical trials in more than 900 patients concluded that alpha-blockers increase the rate of spontaneous stone passage by 44% [48].

Moreover, α1-blockers reduce the need for analgesia by decreasing the frequency of peristaltic contractions in the obstructed ureteral tract, thus decreasing the frequency of ureteral colic [49]. There may be a double action of tamsulosin on the control of pain associated with ureteral colic; one on the smooth muscle, preventing spasm, and a second on C-fibers or sympathetic postganglionic neurons, which also block pain conduction to the CNS [50]. In addition, tamsulosin drastically decreases the need for hospitalization (10% vs 27.5%), as well as the need for endoscopic procedures (0 vs 13%) [31].

Calcium channel blockers

The primary functional anatomic unit of the ureter is the smooth muscle cell, which functions in response to changes in calcium ion concentration. At the most fundamental level, an increase in calcium concentration results in relaxation. Ureteral stones induce ureteral spasm, which results in arrest of stone passage. Studies in both animal and human ureters show that calcium antagonists, namely nifedipine, inhibit the quick phasic contractions without affecting tonic activity [42]. Calcium channel blockers such as nifedipine represent a valid and well-established pharmacologic treatment for urolithiasis owing to their spasmolytic action on the ureter.

Porpiglia *et al.* showed that medical treatment with nifedipine and deflazacort was both safe and effective, as evidenced by increased stone expulsion rate, decreased expulsion time, and reduced need for analgesic therapy [42]. Borghi *et al*. may have provided the most compelling evidence for the isolated effect of nifedipine when they compared nifedipine plus methylprednisolone with prednisolone alone in ureteral stones of up to 15 mm, and reported a success rate of 87% in the nifedipine arm compared with 65% in the control arm [51].

Two studies have compared alpha-blockade with calcium channel blockade with regard to spontaneous stone passage, with both finding an advantage for tamsulosin. Dellabella *et al.* evaluated patients with ureteral stones of greater than 4 mm and found tamsulosin to be the most effective, with a 97% success rate and an average of 72 h to passage compared with 77% for nifedipine, with an average of 120 h to passage [50]. Porpiglia *et al*. compared tamsulosin plus deflazacort with nifedipine plus deflazacort in a control group. Although not as significant as the findings in the study by Dellabella *et al.*, there was a slight advantage of tamsulosin over nifedipine for overall effect (85% vs 80%) and days to passage (7.7 days vs 9.3 days) [52].

Nifedipine blocks all ureteral contraction, while tamsulosin significantly reduces it, but still maintains some baseline activity. Thus, both agents work well to block the disorganized counteractive contractile activity associated with ureteral spasm, but the possibility of maintaining some degree of antegrade peristalsis allowed by alpha-blockade may explain the slight advantage [32]. Therefore, it is advocated to use tamsulosin as a first-line approach for the outpatient management of patients with distal ureteral stones.

Combination therapy

Based on data that suggest a higher rate of spontaneous stone passage, fewer days lost from work, and fewer surgical procedures, some urologists advocate a more aggressive medical approach. This treatment plan is intended for short-term use only but may benefit selected patients who can take medications reliably. A combination of drugs can be used together to improve the chances of spontaneous stone passage and alleviate renal colic discomfort.

Typically used combination therapy to facilitate spontaneous expulsion of urinary calculi consists of:

- Ketorolac or similar NSAID for 5 days;
- Tamsulosin or nifedipine for 7 days;
- Levofloxacin or trimethoprim/sulfamethoxazole for 7 days;
- An oral opioid pain medication as needed for breakthrough pain;
- Metoclopramide or prochlorperazine as needed for control of nausea.

Most ER physicians (76%) use ketorolac for pain management in renal colic, either alone (42.3%) or in combination with morphine (33.7%) [1]. A double-blind, randomized controlled trial demonstrated that the combination of intravenous ketorolac and morphine was superior at reducing pain scores and the need for rescue morphine compared with single-agent therapy [53].

Combination therapy may also increase the efficacy of expulsive therapy. Both ureteral spasm and edema play a role in preventing stone passage. In this regard, the combination of nifedipine (an antispasmodic) and a corticosteroid (antiedema agent) is recognized to be well-tolerated and effective in promoting ureteral stone passage [30].

Because it is widely recognized that infection within the ureter is a possible cause of calculus retention, it seems advisable to include an antibiotic in the standard approach to the patient with a symptomatic ureteral stone. One week of levofloxacin 250 mg could be an appropriate and reasonable measure in this setting [31].

Straining the urine

Stone analysis is extremely important in the evaluation of a patient with urolithiasis for stone preventive therapy. Knowing when a calculus is going to pass is impossible, regardless of its size or location. Therefore, straining of the urine of patients on MET should be continued until the stone actually is collected.

CHAPTER 60
Anesthesia for the Endourologic Management of Stone Disease

John Di Capua, Harold Kim, Kenneth Cordero & Beatrice Saldana Ferretti
Long Island Jewish Medical Center, New Hyde Park, NY, USA

Percutaneous nephrolithotomy

Percutaneous nephrolithotomy (PCNL) is a less invasive alternative for urologists to remove large renal calculi in place of open surgical nephrotomy. The advantages of PCNL have been well documented and include shorter operative time, a quicker recovery period, and less post-operative pain when compared to an open procedure. It is an attractive choice for renal stones that are not amenable to other removal techniques, such as extracorporeal shock-wave lithotripsy (ESWL).

The essential components of PCNL involve a combination of technologies (e.g. ultrasound and fluoroscopic imaging, nephroscopes, and lithotripters), which are used to percutaneously access the renal pelvis so that large stones can be accessed, disrupted, and removed. Other renal disease states, from renal masses to uretero-pelvic strictures, can additionally be addressed using the same underlying techniques [1]. The following discussion will focus on PCNL, as it is one of the more challenging endourology cases that anesthesiologists encounter and also encompasses the considerations for a variety of procedures involving percutaneous procedures of the kidney.

Anesthetic considerations

The patient who presents to the operating room for PCNL has been determined by the urologist to have a renal stone that is not amenable to ESWL. The choice of PCNL over ESWL can be dictated by the large size of the stone (i.e. staghorn calculus) or because the location of the stone in the kidney does not make it accessible for shock-wave therapy. Another factor pertains to the obese patient, whose body habitus is such that the distance from the skin to the kidney makes ESWL ineffective. The prospective PCNL patient will often present with some combination of both of these issues, which can confound the anesthetic plan even further.

Staghorn calculi are, by definition, large stones that involve at least two calyces. Their removal is a labor-intensive task for the urologist using percutaneous access to break up the stone and remove the pieces, occasionally requiring more than one tract to access the entire stone [2]. Larger stones generally require longer operating time with concomitant blood loss. The surgeon, in conjunction with the anesthesiologist, may choose to perform the procedure in "stages" in cases of calculi whose extraction are anticipated to be particularly difficult. This allows the patient to recover and stabilize rather than exposing them to one prolonged surgical stress.

The prevalence of obesity, morbid or otherwise, is increasingly common in the current patient population. Today's anesthesiologist is acutely aware of the increased morbidity and mortality for obese patients undergoing surgical procedures as well as the coexisting disease states that obesity often heralds. It is common knowledge that obese patients are at higher risk for diseases such as coronary artery disease, hypertension, and diabetes. Obese patients are high risk from an anesthetic standpoint because obesity adversely affects all organ systems (Table 60.1) [3].

Smith's Textbook of Endourology, Third Edition. Edited by Arthur D. Smith, Gopal H. Badlani, Glenn M. Preminger, Louis R. Kavoussi.

Table 60.1 Disorders associated with obesity [1].

Insulin resistance/ hyperinsulinemia	Asthma
Type 2 diabetes	Sleep apnea
Hypertension	Breathing difficulties
Dyslipidemia	Complications of pregnancy
Gallbladder disease	Menstrual irregularities
Cancer (prostate, endometria, uterine, cervical, ovarian, colon, kidney, gallbladder, and postmenopausal breast)	Hirsutism
Premature death	Increased surgical risk
Osteoarthritis	Psychologic distress
Stroke	

It is important to note that although obesity has an impact on the perioperative risk factors, patients undergoing PCNL have similar outcomes, regardless of their body mass index (BMI) [4].

Preoperative evaluation

The preanesthetic evaluation begins with the history and physical examination. PCNL should be considered a "moderate-to-high impact" surgical procedure because of both the location and potential for significant blood loss. All of the prospective patient's disease states should be identified and treated to ensure that the patient is "medically optimized" prior to surgery. Diabetic patients should have their blood sugar under adequate control. Patients with cardiovascular disease should have their blood pressure medically optimized and undergo preoperative studies assessing cardiac function and risk to prevent morbidity from cardiac ischemia.

Obese (BMI > $30\,kg/m^2$) patients are of special interest in the preanesthetic evaluation for PCNL because they have a higher incidence of renal calculi as well as obstructive sleep apnea (OSA) than the general population [5]. A yes/no format questionnaire such as STOP (Table 60.2) can assist in screening patients suspected of having OSA [6]. Two or more "yes" responses from the patient indicate a high likelihood of OSA, warranting that sleep studies be performed as part of the medical clearance. If a sleep study has not been performed in a patient who has a high likelihood of sleep apnea, extra monitoring as part of OSA precautions should be used in the perioperative period.

Anesthetic choice and perioperative monitoring

General endotracheal anesthesia (GETA) is the mainstay anesthetic technique for patients undergoing PCNL.

Table 60.2 STOP questionnaire.

1. **S**noring. Do you snore loudly (louder than talking or loud enough to be heard through closed doors)?
2. **T**ired. Do you often feel tired, fatigued, or sleepy during daytime?
3. **O**bserved. Has anyone observed you stop breathing during your sleep?
4. Blood **p**ressure. Do you have or are you being treated for high blood pressure?

The anesthesiologist needs to give special consideration to the potentially difficult airway in the obese patient with or without OSA [7], necessitating the use of special equipment (e.g. fiberoptic bronchoscope or glide scope) or extra personnel when inducing GETA. GETA allows the anesthesiologist to secure the patient's airway under controlled conditions prior to the patient being positioned in the prone position (most common) for the procedure. Due to the fact that the kidneys normally move with the respiratory cycle, the anesthesiologist's ability to control tidal volume and respiratory rate under GETA can improve the urologist's ability to successfully access the renal pelvis in PCNL [8].

Although there is increasing interest in the use of a laryngeal mask airway (LMA) for patients undergoing procedures in the prone position [9], the anesthesiologist should be extremely selective and cautious when considering its use in PCNL. Having the patient intubated with muscle relaxation allows the anesthesiologist to control the patient's ventilatory parameters, compensating for metabolic acid–base derangements, which may occur during the procedure. More importantly, endotracheal intubation offers a measure of protection from aspiration that an LMA cannot in cases of high-risk [e.g. obese, history of gastroesophageal reflux disease (GERD)] anesthetized patients.

Pain sensation for the kidney and ureter correspond to the T8–L2 sensory dermatomes and, as such, are amenable to neuraxial blockade (spinal or epidural blockade). Spinal anesthesia for PCNL has been shown to be an effective alternative to GETA when a low dose of hyperbaric bupivacaine is administered in the lateral position to achieve a unilateral block with negligible hemodynamic side effects [10, 11]. The epidural component of a combined spinal–epidural technique allows the practitioner to adjust the anesthetic level and maintain it for longer periods, resulting in decreased postoperative pain when compared to general anesthesia alone [12]. Low-dose intrathecal/epidural opiates can be used in the neuraxial space to improve patient satisfaction [10–13]. While neuraxial anesthesia is an attractive alternative to GETA, routine usage should be tempered by

other patient considerations, such as the anticipated duration and difficulty of the PCNL. GETA should be chosen for the safety and control of a secured airway in cases where large blood loss and hemodynamic changes with aggressive fluid resuscitation are anticipated.

The use and safety of preoperative medication to provide pre-emptive analgesia should be considered as an adjunct to improve patient satisfaction with postoperative pain management. Nonsteroidal anti-inflammatory drugs (NSAIDs) and selective cyclo-oxygenase inhibitors have been shown to decrease postoperative narcotic consumption in a wide variety of procedures [13]. The combined use of paracetamol, parecoxib, epidural lidocaine/morphine, and local anesthetic infiltration has been shown to be effective for PCNL with minimal postoperative pain [14]. Indeed, the use of 0.25% bupivacaine in the peritubal tract from the kidney to incision alleviated postoperative pain in PCNL performed under general anesthesia [15, 16], as well as improved ventilatory function in the immediate postoperative period [17].

Choice of agents in general anesthesia

A balanced technique is commonly used for patients undergoing PCNL under general anesthesia. The elements of a balanced maintenance anesthetic are a potent inhalation agent (e.g. isoflurane, sevoflurane), muscle relaxant (e.g. rocuronium, cisatracurium), and intravenous narcotics (e.g. fentanyl, morphine). Nitrous oxide should be utilized with caution as it can cause bowel distention, which theoretically increases the chance of injury during PCNL. Morphine undergoes hepatic metabolism and one of its metabolites, morphine-6-glucuronide (10%), is more potent than morphine itself. Morphine-6-glucuronide (10%) can prolong the clinical effect of morphine when administered to a patient with severe renal dysfunction [glomerular filtration rate (GFR) < 50)], necessitating dose reduction or use of another narcotic in these patients. Long-acting muscle relaxants such as pancuronium similarly undergo renal elimination and should be used with caution in patients with severe renal dysfunction.

Propofol is a short-acting sedative/hypnotic medication commonly used for induction of general anesthesia and sedation. Propofol is also included in most regimens of total intravenous anesthesia (TIVA), where general anesthesia is maintained without the aid of a potent inhalational agent. In comparison to isoflurane, propofol can lead to a significant reduction in cardiac index when patients are turned from the supine to prone position [18]. This decrease in cardiac index can result in higher than expected propofol levels, increasing the possibility of overdose in the prone position [19]. Among patients undergoing PCNL, those receiving sevoflurane had higher serum concentrations of renin, aldosterone, and adrenocorticotrophic hormone than patients receiving TIVA with propofol and alfentanyl [20].

Dexmedetomidine is an alpha-2 adrenergic receptor antagonist, which has sedative, anxiolytic, and analgesic properties with minimal respiratory depression. It has a wide variety of applications as a sedative and adjunct for general anesthesia, and its favorable respiratory profile also makes it a good candidate for use in the obese population. Dexmedetomidine can be safely used in patients with severe renal impairment [21]. Hypotension with administration should be considered in patients with borderline cardiac function.

The routine use of intra-arterial pressure monitoring (a-line) in addition to use of standard monitors (electrocardiogram, pulse oximetry, noninvasive blood pressure, gas monitors) is a reasonable consideration for the anesthesiologist. The use of an arterial line allows for realtime assessment of the patient's blood pressure and ready access to blood samples, making information about the patient's electrolytes, acid–base balance, oxygenation, and blood volume obtainable at multiple points throughout the PCNL. The addition of a central venous pressure line (CVP) can help with rapid intravenous volume resuscitation as well as a monitor of the patient's volume status. All invasive lines should be secured prior to placing the patient in the prone position in anticipation of the PCNL.

Positioning

PCNL is typically performed with the patient in the prone position to provide access to the kidneys. Chest rolls are used to support the patient and flatten lumbar spine lordosis, thus facilitating access to the kidney by the surgeon [1]. When positioning the patient prior to the procedure, the surgical team (i.e. anesthesia provider, surgeon, and circulating nurse) should take care to avoid direct pressure on peripheral nerves (e.g. ulnar nerve at the elbow) and arms should be positioned less than 90° at the shoulder to prevent stretch of the brachial plexus. Ocular injury is an exceedingly rare but devastating injury. It can occur when direct pressure is placed on the orbit or can alternatively be due to decreased venous return from the head associated with prone positioning [22]. Coexisting conditions such as diabetes, peripheral vascular disease, hypertension, and anemia (chronic or as a byproduct of surgery) can also contribute to the risk of perioperative visual loss [23].

To limit the possibility of cervical spine injury, the anesthesiologist should take special care when positioning the patient in the prone position to ensure that the neck is maintained in the neutral position, especially in patients with known disc disease. An additional consequence of moving the patient from the supine to prone

position is the possibility of flexion and extension of the neck, as well as rotation of the head, which can cause migration of the tip of the endotracheal tube (ETT) within the trachea [24]. The position of the ETT should be confirmed by the anesthesiologist to ensure that is has not shifted once the prone position is achieved. If there is any question as to the position of the ETT, the placement can be assessed via fluoroscopy since it is readily available as part of the equipment required for PCNL [25].

The physiology of the anesthetized patient in the prone position shows an improvement in pulmonary function, notably in functional residual capacity (FRC), lung compliance, and oxygenation in obese and non-obese patients, in comparison to the supine position [26]. Slight decreases in cardiac index are noted with renal blood flow being preserved [27]. The increased external pressure on the abdomen compresses the abdominal contents, causing increased venous pressure. Patients in the prone position have decreased venous return from the head, which can lead to facial and airway edema. This is time- and pressure-dependant, exacerbated by the degree of fluid resuscitation required during the procedure

Although the majority of PCNL procedures are performed with the patient in the prone position, it has also been successfully carried out with patients in the lateral decubitus and supine positions, using both regional and general anesthetic techniques. The lateral decubitus position combined with neuraxial anesthesia allows the obese patient's abdominal pressure to be displaced laterally, which helps ventilatory function in a patient who is breathing spontaneously [28]. Though supine positioning for PCNL has the advantage of not requiring the repositioning of obese patients, it is generally associated with longer operative times, similar bleeding rates, and worse stone-free rates than prone PCNL [29].

Blood loss and urine output monitoring

With regard to fluid management, the operating field for PCNL is a black box from the anesthesiologist's point of view, thereby emphasizing the need for invasive monitoring. For most other surgical procedures, the anesthesiologist will monitor the blood and urine output to guide volume resuscitation of the patient. The anesthesiologist can take note of the amount of blood lost on the field or in the suction canister and measure urine output via a Foley catheter. In PCNL, however, it is almost impossible to objectively assess blood loss and urine output. The surgical field is small, consisting of a sheath that gives the surgeon partial visualization of a portion of the renal pelvis. The surgeon also uses copious amounts of irrigant to help with visualization of the renal pelvis by washing away blood and debris. The consequence of irrigation during PCNL is that blood loss and urine output are also washed from the surgical field and can therefore not be measured in any objective manner.

The vast majority of PCNL uses isotonic saline as the irrigant to avoid the electrolyte disturbances, namely hyponatremia, which are seen in post-transurethral resection of the prostate (TURP) syndrome where hypotonic solutions are utilized for visualization. Most of the irrigant in PCNL washes out of the surgical field and out of the patient. Fluid can, however, extravasate into the retroperitoneal space, resulting in delayed absorption and possible infection secondary to contamination from bacteria-laden calculus [30]. Fluid can also be directly absorbed through surgical disruption of veins, which, though typically not clinically significant, may result in fluid overload in patients with cardiopulmonary disease, renal insufficiency, and in the pediatric population, mandating extra caution in these patient populations [31].

Fluid resuscitation

For the anesthesiologist caring for a patient undergoing PCNL, the inclusion of an arterial line and/or CVP monitors allows for a measure of safety. There should always be blood products available for a PCNL due to the constantly present risk of bleeding. The anesthesia practitioner should also be aware that irrigant can be passively absorbed into the venous system, thereby increasing intravascular volume.

Hypothermia

The anesthesiologist taking care of the patient undergoing PCNL should closely monitor the patient's core temperature. In the anesthetized patient, the esophageal temperature probe is a relatively noninvasive and reliable source for core temperature measurement, second to a blood temperature from a pulmonary artery catheter [32]. Even though PCNL is not considered an open procedure, there is still the potential for the patient to become hypothermic due to continuous irrigation with below body temperature fluid by the surgeon to visualize the renal pelvis. When compared to other urologic procedures utilizing irrigation fluid [TURP, transurethral resection of bladder tumor (TURBT), cystoscopy], PCNL patients have the greatest drop in core temperature [33].

General anesthesia interferes with the body's normal thermoregulation mechanisms. The patient will often shiver to generate heat upon emergence from anesthesia. Hypothermia-induced shivering in the postoperative setting increases oxygen consumption by up to 400% [34]. Frank *et al*. noted that mild hypothermia of

1.3°C can triple the rate of adverse myocardial outcomes in high-risk patients [35]. Mild hypothermia of less than 1°C also can cause platelet dysfunction and coagulopathy, increasing blood loss by approximately 16% and increasing the relative transfusion risk by approximately 22% [36]. Hypothermia is linked to an increased incidence of delayed wound healing and infection, extending the length of hospitalization [37].

During PCNL, it is imperative that the anesthesiologist monitors the patient's temperature and aggressively warms the patient using fluid warmers and forced air warming blankets. Increasing ambient room temperature and prewarming the patient prior to surgery can help prevent patient hypothermia. Warming of irrigant to body temperature can play a crucial role in reducing the degree of hypothermia in PCNL [33].

Potential complications

Percutaneous access to the kidney is a procedure that is performed with imaging assistance rather than under direct visualization. As such, the possibility of unintended injury exists for anatomically close structures. These complications are covered in Chapters 30-–32, but two are especially pertinent to the intraoperative anesthetic management of percutaneous stone extractions. Bleeding requiring transfusion is the most common complication of PCNL and, as such, reinforces the need for communication with the surgeon, frequent assessment of hemoglobin/hematocrit, and availability of blood products should the patient require transfusion. Organ injury requiring surgical intervention is exceedingly rare in experienced hands, but the anesthesiologist should nonetheless be alert to the remote possibility of a lung injury. This is more common in the supracostal approach and can cause a hemothorax or pneumothorax requiring insertion of chest tube to prevent respiratory decompensation [38].

Emergence

The vast majority of patients undergoing PCNL are allowed to emerge from general anesthesia and be extubated in the operating room following the completion of the procedure. For patient safety, the anesthesiologist will occasionally decide to keep the patient intubated for a period of time after PCNL. This additional delay allows the anesthesiologist time to optimize the patient physiologically, vastly improving the conditions for a safe extubation. Issues such as hypothermia, electrolyte imbalances, and the patient's volume status can be assessed and treated as needed with active warming devices, fluid, and blood administration. Postoperative intubation also allows for the patient to be positioned in the supine, head-up position, allowing gravity to alleviate head and airway swelling, which may occur if a patient is in the prone position for an extended period of time during PCNL. A positive cuff-leak test (absence of a leak around an ETT with the cuff deflated) can be used to help determine whether the patient is at a high-risk for upper airway obstruction [39]. Corticosteroids may also be used to help decrease airway swelling and improve the chances of successful extubation [40].

Postoperative care

The postoperative care of the patient who has undergone PCNL should mirror the care of any other patient recovering from any other significant surgical procedure. Owing to a smaller degree of tissue disruption, the PCNL patient should have considerably less pain medicine requirements than patients who have had renal procedures via laparotomy.

Patients with OSA will warrant close observation in the postoperative setting because they are disposed to narcotic-exacerbated hypopneic desaturation and are also at increased risk for sustained arrhythmias and hypertension [41]. These patients may require continuous monitoring overnight in the postanesthesia (PACU) or intensive care unit (ICU) setting as deemed appropriate by the critical care attending. The treatment of OSA in the postoperative period may warrant the use of a continuous positive airway pressure device (CPAP), which may be useful in improving the patient's oxygenation and hemodynamic profile, even if CPAP was not in the preoperative period, by helping to support the patency of the patient's airway [7].

The care provider in the recovery area should be aware that postoperative fever after PCNL is a potential harbinger of urosepsis, which can occur in 0.97–4.7% of patients [42]. Risk factors for post-PCNL fevers include female sex (higher incidence of urinary tract infections) and the presence of a nephrostomy tube (foreign object) [43]. Patients with negative preoperative urine cultures can have preoperative renal stones, which harbor bacteria whose release into the bloodstream is facilitated by the disruption of calculus, resulting in bacteremia and potentially urosepsis [44]. For a patient who has undergone PCNL, the postanesthetic management of fevers consists of supportive measures (fluids, positive inotropes, as necessary), judicious use of antibiotics, removal of the infectious load (foreign bodies and draining urine), and specific sepsis therapy (e.g. hydrocortisone for pituitary/adrenal insufficiency) [45].

Extracorporeal shock-wave lithotripsy

ESWL has undergone significant changes and developments since its introduction in 1980. It has advantages

over other forms of lithotripsy, namely the effectiveness of stone fragmentation, simplicity of use, low morbidity, and low mortality. This procedure is the treatment of choice for fragmentation of kidney stones located in the upper portion of the ureter and kidney [46].

The first-generation of lithotripters (Dornier HM -3) used a water bath in a steel tub and a metal gantry chair to support the patient suspended in a sitting position [46]. Second- and third-generation lithotripters (Dornier HM-4, Siemens) eliminated the water bath [46]. However, all lithotripters consists of three components; a shock-wave generator (spark plug), a system to focus the shock wave, and an imaging device to visualize and localize the stone in focus.

The electric energy (from the spark plug or electrode) creates a spark which generates a loud noise, intense heat, and explosive vaporization of water. The sudden expansion of air bubbles creates a pressure wave (shock wave). The shock wave is focused to a focal point called F2 focus (the tip of the electrode is the F1 focus). The shock wave travels through water and body tissues before it reaches the stone. When it reaches the entry surface of the stone, it is transmitted across and exits on the opposite surface of the stone. The repeated shock waves cause the breakdown of the stone's structure, producing small fragments which are passed in the urine. For effective stone disintegration, shock waves should reach the stone unimpeded. Also, for shock waves to be most effective, the stone should remain in the F2 focus during treatment [46, 47]. Kidney stones follow diaphragmatic movement during spontaneous ventilation, which can shift the F2 focus and cause difficulties for stone disintegration [46, 47]. To minimize stone movement, general anesthesia, using low tidal volumes with intermittent breath holding, is recommended during lithotripsy. Theoretical advantages of using controlled ventilation, in addition to reducing stone mobility, are decreased operating room time and shock-energy requirements, resulting in less perinephric trauma and side effects [48]. Intermittent positive pressure ventilation and high frequency jet ventilation have been compared in a few studies and show no difference in successful stone ablation [48]. The high density of the energy shock wave has a significantly greater pain impact with the first-generation lithotripters as it passes through the skin, muscles, and deeper structures, such as subcostal nerves and the kidney capsule [48, 49]. The three factors that influence the propagation of pain at this site are the pressure of the shock waves, size of the focal area, and shock wave distribution. The location and size of the stone have an additional impact. Stones in the renal pelvis are more painful than stones in the lower ureter [48]. General anesthesia as well as spinal and epidural anesthesia are often required for this procedure.

Water baths are no longer produced due to the advances of second- and third- generation lithotripters. However, older first-generation lithotripters continue to be used when second- and third-generation lithotripters fail because of the higher shock energy they produce. Pain from second- and third-generation lithotripters is considered mild to moderate when compared to that of the first-generation lithotripters because the shock waves are of lesser intensity [50]. Tissue infiltrations with local anesthetics, intravenous sedation, and paravertebral blocks have all been used in the outpatient setting with good results. Deep sedation and general anesthesia with an LMA or endotracheal tube are still a consideration for the large and difficult stones.

First-generation lithotripters and physiology of water immersion

Water immersion causes significant physiologic changes to the patient, particularly for the cardiovascular, respiratory, and endocrine systems. The cardiovascular changes are related to the depth of immersion. The central blood volume is increased by redistribution of the venous blood and extracellular fluid from the legs and arms in the sitting position, while the central venous pressure is also elevated due to the water pressure against the thoracic wall [51]. The plasma volume will increase 7%, as hydrostatic pressure favors capillary reabsorption [51]. Cardiac output is increased as a result of the elevations in stroke volume and end-diastolic volume. Bradycardia has also been reported, and may be a compensatory response to the increases in cardiac output and decreases in peripheral vascular resistance [52, 53].

Left atrial distention seen during these water immersion-induced changes will cause increases in diuresis by endocrine pathways, causing stimulation of the volume and pressure receptors, particularly carotid and aortic baroreceptors [54–60] Release of atrial natriuretic peptide causes an increase in diuresis, kaliuresis, and natriuresis. The release of arginine vasopressin is suppressed as a result of increased arterial pulse pressure and left atrial distention. Renin–aldosterone and norepinephrine levels are additional hormones that may be suppressed during immersion and act as mediators.

With regard to respiratory function, blood flow is increased in all zones of the lungs with improvements in the ventilation–perfusion relationship [61 –63]. Vital capacity and expiratory reserve volume (ERV) decrease significantly, while tidal volume (Vt) remains unchanged during immersion [64]. The average reduction in vital capacity and FRC is approximately 30% [64]. There is a marked increase in the dynamic work of breathing (e.g. rapid and shallow breaths) during submersion to the

neck, which can be attributed to an increase in flow resistance of the airways as well as an increase in transdiaphragmatic pressure [65]. Patients with preexisting pulmonary and cardiac dysfunction may experience impaired ventilation and oxygenation during water immersion. Therefore, in such patients, second- and third-generation lithotripters are recommended to avoid the physiologic effects of water immersion.

Anesthetic choice

Anesthetic regimens used successfully for lithotripsy include general anesthesia, epidural anesthesia, spinal anesthesia, flank infiltration with or without intercostal blocks, paravertebral blocks (thoracic and lumbar), and analgesia–sedation, with or without topical anesthetic [66–74]. Epidural and spinal anesthesia offer reliable analgesia, and have been frequently used with first-generation lithotripters as well as in patients with severe cardiovascular and pulmonary diseases due to its minimal effect on patient ventilation. For epidural anesthesia, a catheter is placed in the lumbar or thoracic spine in the potential space between the dura and the ligamentum flavum. Local anesthetic can be titrated via the catheter to achieve a desired motor and sensory block; a level of sensory block between T6 and T8 is desirable for kidney stones located in the upper pole. Either lidocaine 2% in a bolus of 15 mL or bupivacaine concentration of 0.25% or 0.5 % can provide excellent anesthesia for approximately 2–4 h, and can be supplemented via catheter if more analgesia is necessary. The extent and intensity of the block can be titrated and maintained as opposed to a single spinal injection. Spinal anesthesia involves direct injection of local anesthetic via a thin needle into the intrathecal space at the level of the lumbar spine below the level where the spine splits into the cauda equina (L1–2). Typical local anesthetics for spinal anesthesia include bupivacaine 0.75% and tetracaine 0.5%, both of which are long-acting anesthetics. The use of lidocaine (shorter acting compared to bupivacaine or tetracaine) for spinal anesthesia is contraindicated due to neurotoxicity. Cauda equina and transient radicular irritation are two complications from the use of lidocaine when injected into the cerebrospinal fluid [75, 76]. Transient radicular irritation is characterized by severe back and buttock pain with no localized nerve damage, and its incidence is seven times greater with lidocaine when compared to bupivacaine and other local anesthetics. The symptoms tend to resolve by the 10th day after spinal anesthesia with no sequelae [75–77].

Administration of local anesthesia in the spinal or epidural space results in a chemical sympathectomy that is well tolerated by most individuals, but can become clinically significant in patients with poor cardiovascular reserve. In these patients symptoms include vasodilation of the lower extremities, resulting in decreased preload as well as afterload, which in turn causes a reduction in cardiac output. Judicious pretreatment with an intravenous fluid bolus can maintain the preload as well as attenuate the precipitous drop in blood pressure. The use of vasoactive medications (e.g. phenylephrine and ephedrine) can also be utilized to augment the blood pressure and systemic vascular resistance. The ability to gradually raise an anesthetic level with an epidural should be considered in the patients in whom rapid hemodynamic changes are undesirable. Disadvantages of using neuraxial anesthesia for outpatient lithotripsy include the time to achieve an adequate level of anesthesia or analgesia, longer recovery phase, and urinary retention. Epidural hematoma can occur and become a devastating complication in the patient with coagulopathies or those receiving anticoagulation. Therefore, neuraxial regional anesthesia is contraindicated in patients with altered coagulation.

There are no absolute indications for spinal or epidural anesthesia, but patients can benefit from these techniques in certain clinical situations. Evidence indicates that neuraxial anesthetic techniques can have improved outcomes in high-risk populations [78]. Benefits of regional anesthesia include a blunting of the stress response to surgery, decreased morbidity, and decreased mortality. When analgesia is extended into the postoperative period, it can reduce the incidence of postoperative thromboembolism in high-risk patients [e.g. morbid obesity, chronic obstructive pulmonary disease (COPD), cardiomyopathy) [78].

Second- and third-generation lithotripters emit shock waves of lower intensity, with lower efficacy as well as smaller focal points, occasionally necessitating additional treatment rounds. As already mentioned, pain is generally less than with the first-generation lithotripters. Analgesia and sedation are still required for patient comfort, as is keeping patient movement to a minimum [79, 80].

Risk factors predictive for increased pain during ESWL include patients of young age, rib-projected stones, recurrent treatments, homogenous stones, and patients with anxiety and/or depression. These patients may exhibit a higher analgesic requirement [81].

Intravenous sedation is a viable alternative for the second- and third-generation lithotripters. The use of intravenous sedation alone provides for a faster recovery period and fewer side effects than found with either regional or general anesthesia [68, 69, 82]. Sedation is commonly achieved utilizing short-acting anesthetic agents. NSAIDs such as ketorolac have anti-inflammatory effects and facilitate stone removal by inducing ureteral relaxation [82]. When used in combination with short-

acting opiates such as fentanyl or alfentanil, adequate analgesia can be achieved. COX II inhibitors can also prevent renal colic pain and are useful as a pre-emptive analgesic prior to ESWL [82, 83]. The addition of an adjunct such as midazolam can be used for anxiolysis and amnesia in the perioperative period.

A commonly used medication for moderate-to-deep sedation is propofol, an ultra short-acting hypnotic agent that is administered as a bolus or continuous infusion. It is extremely well tolerated by the majority of patients, providing restful sleep, hypnosis, and amnesia. Propofol has no analgesic properties; therefore, titration of opiates such as fentanyl can be useful. Midazolam has an additive effect for sedation when combined with propofol. Advantages of combining various sedatives and analgesics, called balanced anesthesia, include fewer side effects, the ability to titrate sedation in order to avoid involuntary patient movements, short recovery time, and fast hospital discharge [68, 69, 84–94]. This balanced technique is particularly safe and useful for office-based procedures [95].

Dexmedetomidine (Precedex) is an agent that is gaining popularity among anesthesia providers to sedate patients in the operating room. It is a selective alpha-2 agonist, which has sedating and analgesic properties without respiratory depression. The agonist action of the alpha-2 adrenergic receptor in the sympathetic ganglia modulates the release of catecholamine, resulting in a sympatholytic effect and reduction in blood pressure [72, 73]. Dexmedetomidine is an attractive anesthetic choice for select patients with comorbidities such as morbid obesity, severe COPD, OSA, and patients with tolerance to opiates. Dexmedetomidine produces less respiratory depression than propofol, even at maximal doses. Intravenous sedation–analgesia of dexmedetomidine has proven to be safe and effective for outpatient lithotripsy [71, 74]. In combination with opioids such as fentanyl or remifentanil, dexmedetomidine provides excellent analgesia with minimal side effects [71]. Remifentanil is a potent ultra short-acting narcotic with fast onset and fast elimination, which is administered by continuous infusion, often in combination with dexmedetomidine.

Other anesthetic choices for lithotripsy employ the use of local anesthesia infiltration into the flanks and deep lumbar area. Lidocaine or prilocaine are injected subcutaneously in a dose of 20 mL, which appears to offer adequate pain relief, short onset of action, and low toxicity [88–90]. The local anesthetic is placed 1 cm below the 12th, 11th, and 10th rib with a single needle entry at a 45° angle [90]. The analgesic effect can last up to 3 h and is well tolerated by patients. The procedure is easy to perform and cost-effective.

Intercostal nerve blocks [96] are an alternative for analgesia during ESWL. This block uses bupivacaine 0.25% mixed with epinephrine and lidocaine for faster onset of action. Usually 5 mL is injected in each intercostal nerve at the lower border of the corresponding rib between the posterior axillary line and medial to the angle of the rib. The position of the stone is determined in relation to the lumbar spine. This is a relatively easy block to perform and appears to be well accepted by patients, most of whom report only mild soreness [96]. Additional doses of intravenous opioids can supplement the block for patient comfort.

EMLA cream is a eutectic mixture of lidocaine and prilocaine that is for topical use. Application 45 min to 1 h before ESWL provides adequate effect. An occlusive dressing is also necessary after the application in the flanks for effective skin penetration. A combination of this technique with intravenous sedation and use of opioids seems to be better tolerated and offers advantages over EMLA cream alone [86 –97].

Paravertebral (thoracic and lumbar) blocks can provide adequate postoperative pain relief after lithotripsy, reducing the use of opiates both during and after surgery [98]. Alternatively, a nerve stimulator can be used to guide needle placement [99, 100]. The mechanism of action for paravertebral blocks includes direct penetration of the local anesthetic into the spinal nerve with medial extension through the intervertebral foramina [101]. Five milliliters of local anesthetic is administered per paravertebral level. Anesthetic agents most commonly used are ropivacaine 0.5% or bupivacaine 0.25% or 0.5%, both with epinephrine diluted (1:400 000). Ropivacaine has less cardiotoxicity when compared to bupivacaine and therefore is the preferred choice by many anesthesiologists. Side effects or complications of this block include hypotension, inadvertent injection into the epidural space or spinal block, pneumothorax, and nerve injury. This block offers very effective analgesia and can be combined with small doses of sedation for additional patient comfort. The major advantage of this technique is the prolonged postoperative analgesia [98, 102].

Management of cardiac pacemakers and defibrillators

ESWL can induce cardiac arrhythmias by mechanical stress exerted from the high-energy shock wave into the conduction system. Ventricular and supraventricular tachycardia have been described during ESWL [103–105]. Timing during the cardiac cycle is crucial for inducing dysrhythmias. The shock waves can also inhibit pacemaker output when administered asynchronously. New lithotripters are designed to fire 20 ms after the QRS complex (during the absolute refractory period) [105–108]. This practice reduces risk of arrhythmias due to the R on T phenomenon.

Pacemakers and automatic internal cardiac defibrillators (AICD) are complex devices that interact with cardiac function in ways that can significantly influence hemodynamics [107, 108]. They are designed with a high-frequency noise filter to prevent malfunction from the energy interference [106–108]. Electrical inhibition does not appear to be a problem when ESWL discharge is synchronized to follow a pulse generator signal [107, 108]. However, electromagnetic interference is an important cause of pacemaker malfunction. Fortunately, new pacemakers provide improved shielding to protect them against ESWL damage or reprogramming. The advisory practice for perioperative management of patients with pacemakers and automated defibrillators is to avoid the lithotripsy beam near the pulse generator and disable atrial pacing if the lithotripter triggers on the R wave (internal communication with Electrophysiology Departments of North Shore – LIJ Health System, April 2010).

Patients with an AICD and/or a cardiac pacemaker can receive shock-wave lithotripsy and/or undergo surgical procedures that utilize electrocautery, with some important precautions before the procedure [107, 108, – internal communication with Electrophysiology Departments of North Shore – LIJ Health System, April 2010]. It is important to know the type of device, and battery life and its function. Ideally, the patient can provide this information. However, this information is not always available. Fortunately, there are a limited number of companies that manufacture AICD and all of them have telephone resources that can help identify if a patient has one of their devices. In elective situations, the ACID/pacemaker should be evaluated before and after lithotripsy. Pacemakers should be converted to an asynchronous mode (AOO or VOO), if necessary [107, 108, internal communication with Electrophysiology Departments of North Shore – LIJ Health System, April 2010]. Patients with a rate-sensing pacer should have the sensing function turned off. For AICD patients, the defibrillator functions must be turned off before the procedure due to the risk of it either becoming damaged or being triggered during the shock wave, which can trigger ventricular dysrhythmias [107, 108, internal communication with Electrophysiology Departments of North Shore – LIJ Health System, April 2010].

In an emergency, a magnet can be placed over a standalone pacemaker to convert it to an asynchronous mode. However, the use of a magnet should be discouraged whenever there is adequate time to properly interrogate a pacemaker before and after surgery. After the surgical procedure is completed, pacemakers should be interrogated to be sure they have retained the desired settings.

In an emergency, a magnet can be placed over an AICD to turn off its defibrillator functions. However, applying a magnet over an AICD does not produce exactly the same results on the pacemaker functions in all AICDs, particularly in older models [109]. Therefore, if a magnet is used to turn off the defibrillator, the anesthesiologist and surgeon must take the following into account. First, the pacemaker functions of the AICD can be suppressed by electrocautery, which poses risk for those patients who are pacemaker dependent. Therefore, the surgeon should either limit electrocautery bursts to less than 5 s or use a bipolar electrode. Second, the AICD must be interrogated and reprogrammed at the end of the surgical procedure, but before the magnet is removed [109].

When an AICD is turned off, external defibrillator pads should be placed over the patient's chest, once in the operating room. Optimal position may be an important factor in the prevention of adverse outcomes [59, 61]. Anterior and posterior pads should be used with the appropriate energy output in case the patient requires defibrillation [107, internal communication with Electrophysiology Departments of North Shore – LIJ Health System, April 2010]. Patient cardiac rhythm should be monitored at all times, with pacing and/or defibrillation capabilities immediately available for use [107, internal communication with Electrophysiology Departments of North Shore – LIJ Health System, April 2010]. Once the procedure is finished, the device should be turned on to evaluate for functionality and to restore functionality before the patient leaves the operating room [107, internal communication with Electrophysiology Departments of North Shore – LIJ Health System, April 2010].

Turning off an AICD in a patient who is going to have a water bath lithotripsy is complicated by the fact that external defibrillator pads cannot be used safely in water. This specific scenario requires coordination between the anesthesiologist and cardiologist. An acceptable alternative is to have an experienced user of the external AICD programmer remain on standby once the AICD is turned off for the lithotripsy. In an emergency, the AICD could be turned on again to allow safe defibrillation of the wet patient [109].

Anesthesia for ureteroscopy

With the advent of smaller and semi-rigid flexible ureteroscopes, intravenous sedation is favorable for cases of short duration such as cystoscopy and stent insertion. Ureteral stents, renal calculi, and ureteral strictures have been successfully performed using lidocaine 4% gel to anesthetize the urethra. This anesthetic technique has the benefit of faster operating room turnover and faster discharge from hospital [110–116]. Among men, discomfort during rigid ureteroscopy seems to be related to the passage of the instrument through the membranous

urethra and bladder neck [110]. Pain seems to be better tolerated in women having the procedure under local or intravenous sedation [95].

Due to the fact that the kidneys normally move with the respiratory cycle, the stone is only intermittently visualized [46, 47]. Therefore, the anesthesiologist's ability to control tidal volume and respiratory rate under GETA can improve the urologist's ability to successfully fragment ureteral stones. It is imperative that the anesthesiologist and urologist work together to allow concomitant adequate ventilation and intermittent apneic episodes to successfully fragment stones. Urethral trauma with patient movement is a concern during ureteroscopy, emphasizing the importance of selecting an appropriate anesthetic technique for a given patient. If a patient experiences sudden movements under anesthesia with a ureteroscope in use, there is the potential for ureteral trauma or ureteral transection, a potentially devastating and avoidable complication. Selection of anesthetic agent may be tailored to the fact that most of these procedures are performed on an outpatient basis and the patient will be going home on the day of the procedure. However, regardless of the choice of anesthetic technique, it is imperative that the anesthesiologist be vigilant that the patient is adequately anesthetized to avoid such complication.

The urethra receives innervation from the preganglionic sympathetic fibers of the T10–L2 spinal segments. The upper ureter receives parasympathetic input from vagal fibers by means of the celiac plexus and the lower ureter from S2 to S4 [110]. Spinal and epidural anesthesia are rarely the anesthetic choices for ureteroscopy because other modalities offer advantages over neuraxial techniques [110]. However, neuraxial anesthesia remains an option in patients with significantly poor respiratory reserve. General anesthesia has been performed with great success using the LMA, and is a less invasive alternative to endotracheal intubation and is well tolerated by patients for general anesthesia. Sevoflurane and desflurane offer fast onset of action and rapid elimination. Analgesia can be supplemented with small doses of opioids. Compared to regional anesthesia, general anesthesia with an LMA leads to faster patient recovery and discharge [110]. It is an efficient technique for ureteroscopy, cystoscopy, and stent placement in a majority of patients.

The LMA does not protect the airway from the risk of aspiration of gastric content. Therefore, it is important that risk for aspiration be considered when selecting patients for an LMA technique. Factors that increase the risk for aspiration include morbid obesity, liver disease with ascites, diabetes with gastroparesis, pregnancy, GERD, neuromuscular disease, bowel obstruction, and dysphagia. Patients considered at risk for aspiration require GETA or, if possible, regional anesthesia with conscious sedation.

Anesthesia for the patient with spinal cord injury

Patients with spinal cord injury frequently have urologic procedures for stone extraction because they are predisposed to stone formation due to neurogenic bladder and immobilization.

For patients with spinal cord injury, there is a loss of spinal sympathetic discharge modulation, which can produce profound hemodynamic changes [117, 118]. Lesions at the level of T6 and above are associated with a life-threatening, hypertensive emergency, during which uncontrolled sympathetic and parasympathetic hyperactivity occurs in response to stimulation below the level of the spinal lesion [117–119]. This syndrome, called autonomic dysreflexia, results from the lack of supraspinal control of the sympathetic neurons and altered neurotransmission within the spinal cord [119]. Stimuli such as bladder or bowel distention and pain during surgery can trigger severe, uncontrolled hypertension and bradycardia. These patients will experience increases in pulse pressure, sweating, piloerection, vasoconstriction below the level of the spinal lesion, and vasodilation above the spinal lesion. The complications resulting from autonomic dysreflexia include intracranial and retinal hemorrhages, myocardial infarction, coma, and death. Cardiac rhythm anomalies such as atrial fibrillation, ventricular tachycardia, and cardiac arrest can also occur [120].

General and spinal anesthesia blunt the afferent and efferent autonomic neural impulses. These two forms of anesthesia are preferred over other techniques for patients with spinal cord injury. Autonomic dysreflexia can be treated with intravenous ganglion blockers, nitrates, clonidine, and calcium channel blockers. Oral nifedipine given 30 min before cystoscopy has been shown to alleviate the syndrome [121]. Bladder emptying and colonic decompression prior to a surgical procedure can help reduce the risk of developing autonomic dysreflexia.

Conclusions

The patient receiving PCNL presents a challenge for the anesthesiologist. Despite the relatively noninvasive nature of the procedure, there remains the potential for rapid fluid shifts with the patient in the prone position as well as other potential mitigating factors such as hypothermia and possible bacteremia. Close monitoring and attention are essential in both the intra- and postoperative periods, as well as communication with the urologist to ensure the best outcome for the patient.

Anesthesia for ESWL has changed dramatically with advances in lithotripsy. Today, patients with small friable stones can undergo ESWL with intravenous sedation with or without local anesthesia. However, larger stones or stones more resistant to ESWL may require general or neuraxial anesthesia. The eventual anesthetic choice needs to take into account the physical status of the patient, length of procedure, need for minimizing respiratory movement of stone, the need for ureteroscopy, and type of ESWL device utilized. A challenge of increasing frequency is the management of automatic internal cardiac defibrillators during ESWL and/or urologic procedures that utilize frequent bursts of electrocautery. All of these issues can be dealt with safely as long the anesthesiologist and surgeon discuss all of these factors before induction of anesthesia.

CHAPTER 61
Horseshoe Kidney

Wan Wan Yap[1], Tze Wah[1] & Adrian D. Joyce[2]
[1]Department of Radiology, St James' University Hospital, Leeds, UK
[2]Department of Urology, St James' University Hospital, Leeds, UK

Introduction

Renal fusion anomalies can be broadly divided into two distinct types: horseshoe kidneys and cross-fused ectopia. Horseshoe kidneys are the commonest renal anomalies and have been reported to have an incidence of 1 in 400–700 live births in both autopsy and radiographic data [1, 2]. There is a male preponderance for this condition with a male-to-female ratio of 2:1. No genetic predisposition is known and whilst horseshoe kidneys are frequently diagnosed incidentally and in isolation in adult patients, they may be part of a syndrome in the pediatric population. It is estimated that 23% of patients with horseshoe kidneys have other severe associated malformations, which may be gastrointestinal, musculoskeletal , neurologic, or, most commonly, other urogenital anomalies [3]. Several syndromes are commonly linked to horseshoe kidneys, including Down's syndrome, Turner's syndrome and Trisomy 18.

Development

Normal kidney development occurs at the fourth week of gestation from the fusion of the ureteric bud and metanephric blastema. The kidney is originally formed in the pelvic location and ascends with the growth of the body, in particular the sacral and lumbar region. Primitive renal vessels that originate from the pelvic aorta degenerate as the vascular supply gradually arises from the proximal aorta. As the kidneys ascend through the arterial fork, they may be pushed together too closely and become fused at the lower poles. A more recent theory suggests that fusion may be the result of abnormal migration of the posterior nephrogenic cells, which then fuse with the lower poles of the kidneys to form an isthmus [4]. The ascent of the fused lower pole kidneys terminates just below the inferior mesenteric artery and at the level of the L1–L4 vertebral levels (Figure 61.1).

Horseshoe kidneys are located anterior to the aorta and inferior vena cava. The fused lower poles of horseshoe kidneys are bridged by either functional renal tissue or fibrous tissue. Due to the fusion to the lower poles, the renal pelvis fails to rotate medially and consequently remains ventrally located. This results in the ureter exiting the renal pelvis ventrally and more superiorly, and the longitudinal renal axis converges medially [5]. This has important implications in relation to the management of stones in horseshoe kidneys.

Complications and their management

A horseshoe kidney by itself is asymptomatic; however, due to the anatomy of high ureteric insertion, the presence of the isthmus, and the ventral orientation of the renal pelvis, it is more prone to certain complications, which include recurrent infections [6], renal stones, ureteropelvic junction (UPJ) obstruction, vesicoureteric reflux [7], and even renal malignancy.

Smith's Textbook of Endourology, Third Edition. Edited by Arthur D. Smith, Gopal H. Badlani, Glenn M. Preminger, Louis R. Kavoussi.

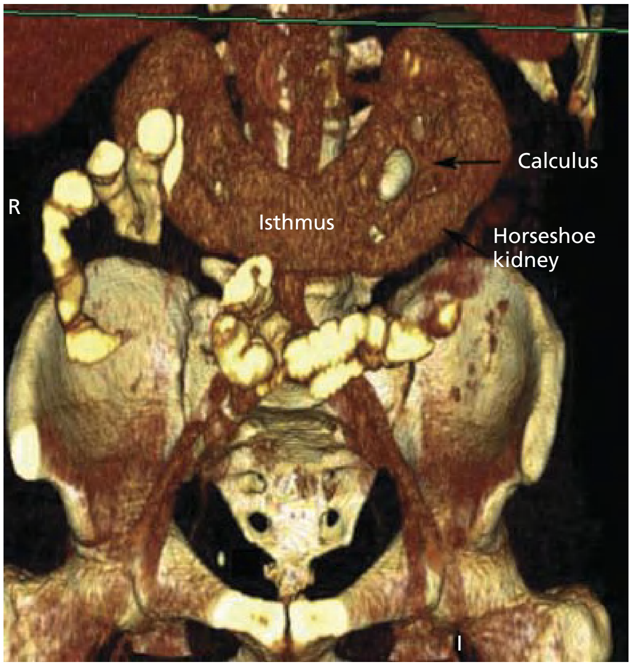

Figure 61.1 Coronal view of a horseshoe kidney 3D reconstruction with a calculus in the left moiety.

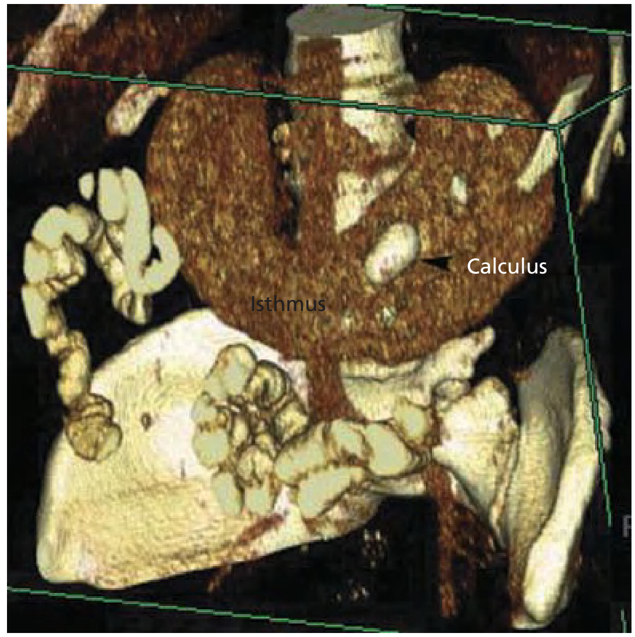

Figure 61.2 Coronal oblique view with 3D reconstruction showing the ventrally orientated lower pole and isthmus.

Urolithiasis

Urolithiasis is the commonest complication related to horseshoe kidney and is estimated to occur in between 21% and 60% of cases [8]. This is likely to be a consequence of impaired urinary drainage, leading to stasis and infection predisposing to calculi formation. The treatment of urolithiasis poses a unique challenge due to the variable vascular and renal anatomy of horseshoe kidneys and their predisposition to multiple and large staghorn-like calculi [3]. The abnormal orientation of the renal pelvicalyceal system further increases the potential complexity for stone management.

Minimally invasive intervention for the treatment of urolithiasis in a horseshoe kidney is now widely accepted, with good stone-free results and low complication rates [9, 10]. However the clinical decision-making process must balance the likelihood of stone-free rates against the intervention risk and potential for complications.

Extracorporeal shock-wave lithotripsy

Extracorporeal shock-wave lithotripsy (ESWL) has revolutionalized the treatment of renal stone disease and has been advocated as the primary treatment modality for stones less than 20 mm in diameter [8]. Sheir *et al.* retrospectively reviewed 198 patients with anomalous kidneys and showed that ESWL is a safe and reliable method of treatment with a stone-free rate of 72% [11]. This is comparable to the stone-free rate of a solitary stone in a normal kidney (72.8%); however, the reported range for stone-free rates in horseshoe kidneys varies between 33% and 79% [12].

The anatomy and orientation of a horseshoe kidney presents a challenge to the use of ESWL as the renal pelvis is venteromedially orientated and approximately a third may have concomitant UPJ obstruction. Locating these calculi can be difficult as the vertebrae may act as an obstacle and there may be associated vertebral anomalies in some patients. The skin–stone distance may also be increased, resulting in difficulty in positioning the focal point (Figure 61.2). Prone position and "blast path" may need to be used to target these awkwardly positioned calculi [13]. A better stone-free result is also achieved when a second-generation lithotripter is used [11]. Concerns have also been raised, due to the high ureteric insertion of the ureter, as to whether fragments post ESWL can pass spontaneously. The most important predictors for failure of ESWL or significant residual calculi needing retreatment are the position, length, and number of stones. Ancillary procedures may need to be used pre ESWL, such as percutaneous nephrostomy, double-J ureteric stents, or ureteral catheterization, and their use should be decided on a case-by-case basis. It is important to emphasize that there have been no prospective studies comparing the different treatment modalities in this group of patients.

Complications post ESWL in horseshoe kidneys are similar to those seen in normal kidneys. Renal colic,

mild hematuria, and urinary tract infection are considered mild and may be treated conservatively and medically. Steinstrasse is a rare but known complication post ESWL and can result in ureteric obstruction requiring endoscopic retrieval of these calculi. The risk factors for steinstrasse post ESWL in a normal kidney are stones greater than 2 cm in a dilated system, proximal located calculi, and the use of a high kilovoltage for disintegration [14].

Percutaenous nephrolithotomy

Percutaneous nephrolithotomy (PCNL) is a well-established technique for the treatment of urolithiasis in normal kidneys and is often used as first-line treatment in horseshoe kidneys, especially when calculi are larger than 2 cm or after failed ESWL.

As described above, the horseshoe kidney lies lower than the normal kidney. The renal pelvis is ventrally orientated and in most cases, the lower poles are connected by isthmus which may be fibrous or viable renal tissue. The long axis of the kidney is orientated in the sagittal plane, such that the posterior calyces are orientated dorsomedially and the frontal row points dorsolaterally. Thirty percent of horseshoe kidneys have a single renal artery on either side [15], but the blood supply is variable with accessory vessels arising from any part of the abdominal aorta, bifurcation or iliac arteries, and inserting into the renal hilum. There are no accessory vessels in the dorsal aspect of the horseshoe kidney [16].

Taking all the above anatomic features into consideration, percutaneous access of horseshoe kidney is relatively safe and is often approached via the most superior calyx. Inadvertent damage to the pleura is uncommon with an upper pole puncture in a low-lying horseshoe kidney. The posterior calyx is relatively easily accessible with a direct puncture in a dorsoventral direction and the puncture site more medially located in comparison to a normally orientated kidney. Apart from several accessory vessels to the isthmus, there are no major blood vessels arising from the dorsal aspect of the kidney. The risk of access-related major vascular hemorrhage is no higher than in normal kidneys.

Access for PCNL can be performed under ultrasound, fluoroscopic, or computed tomography (CT) guidance. The basic principle of achieving an atraumatic puncture of the renal calyx should be adhered to if possible, regardless of the modality used. The safest point of puncture is the middle of the calyx following Brödel's line. However, the superior calyx is usually the chosen puncture site for staghorn calculi or stones within multiple calyces. This is because of anatomic access with a posterior puncture, which allows increased maneuverability of the nephroscope within the collecting system and the option to use flexible instrumentation to access stones in peripheral calyces.

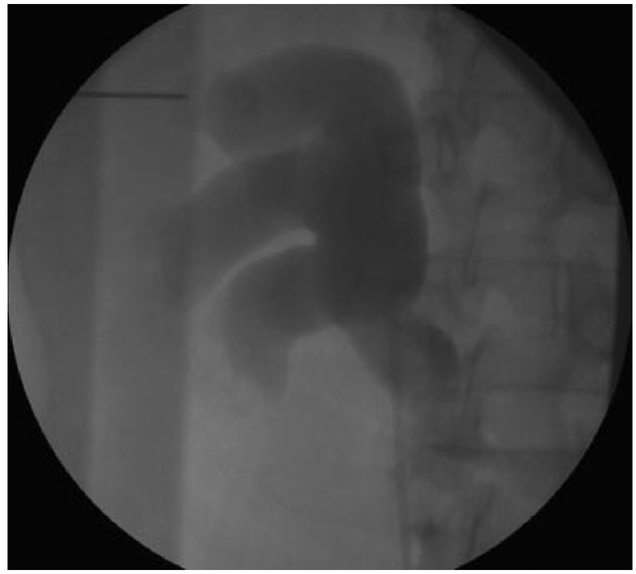

Figure 61.3 18G-sheathed needle is aimed at the calyceal cup.

Ultrasound can be used to guide puncture into the superior calyx if the collecting system is hydronephrotic or predilated with fluid/contrast retrogradely. However, the lower pole is also often poorly delineated and as a consequence, the view of the calyx may be suboptimal to guide access puncture [17].

Fluoroscopic-guided puncture is the standard technique used in our institution. After placing a ureteric catheter, the patient is then turned into the prone position with the C-arm placed vertically. The pelvicalyceal system is distended with contrast and the C-arm can be rotated +30° to –30° to evaluate the calyceal anatomy. An 18G sheath needle is used to puncture the skin and advanced into the desired calyx under fluoroscopic guidance (Figure 61.3). The needle is advanced in increments and aimed at the calyceal cup. When the needle is moving with respiration, the C-arm is then rotated obliquely to an angle such that the length of the needle is visualized and the needle is advanced under fluoroscopic guidance. The needle should be advanced ideally to puncture the epicenter of the calyx and the needle tract should be in the orientation of the infundibulum. As the tract may be longer for horseshoe kidneys, longer instruments may be necessary. As the lower pole and pelvis are more anteriorly facing than is usual, a standard lower pole lateral entry may damage the large anterior division arteries or accessory branches from the iliac artery [18]. Therefore, lower pole calyx puncture is avoided in our practice unless there is no alternative. Once the puncture site is secured, an Amplatz super-stiff guidewire (0.035 inch, 180 cm; Boston Scientific, Natick,

Figure 61.4 Telescopic metal dilator is inserted within the upper pole calyx with an Amplatz super-stiff guidewire in the ureter to anchor the tract.

Figure 61.6 Foley catheter is sited as a covering nephrostomy at the end of the procedure.

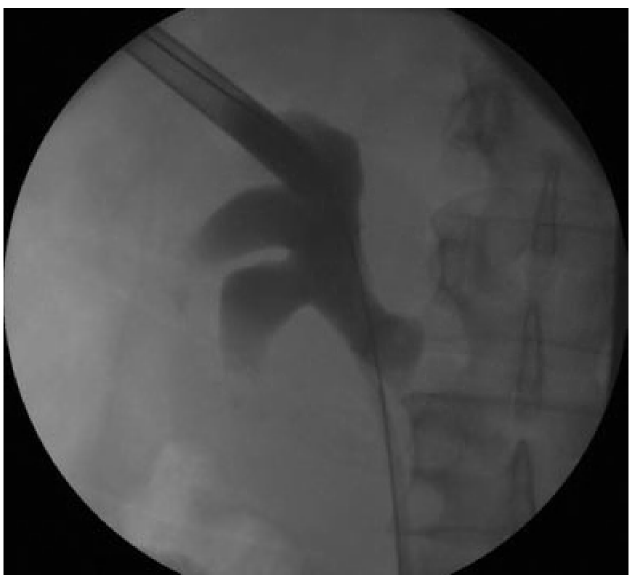

Figure 61.5 26F Amplatz sheath is inserted into the upper pole calyx .

MA, USA) is advanced, preferably down the ureter (Figure 61.4), and the tract is dilated serially with telescopic metal dilators (Olympus, Keymed, Southend-on-Sea, UK) to accommodate the 26F (up to 30F) Amplatz sheath (Cook Urological, Bloomington, IN, USA) (Figure 61.5). A rigid nephroscope is used to remove the calculi, using either an ultrasonic or lithoclast lithotripter to disintegrate the stones. Stones can be removed sequentially through the tract with various stone-grasping devices. At the end of the procedure, we usually site a Foley catheter (20F) as a covering nephrostomy to tamponade the tract for at least 24 h (Figure 61.6). This is then clamped and if the patient is asymptomatic, the nephrostomy is be removed on the ward. A postprocedural nephrostogram is only performed if there is concern with regard to injury or significant distal ureteric stones causing obstruction.

CT-guided access is reserved for complex situations resulting in challenging access due to the patient's associated vertebral anomaly, severe kyphoscoliosis, extreme obesity, or hepatosplenomegaly. A CT scan is normally acquired in a prone position and can also be used for surgical planning prior to PCNL. Retrorenal or posterolateral displacement of the bowel can be associated with horseshoe kidney and the bowel may occasionally act as an obstacle to percutaneous access. In these situations an initial unenhanced CT abdomen and pelvis with 2-mm reconstruction (CTKUB) may be performed as an overview. Subsequent images for CT-guided procedure can be acquired by obtaining a volume of area of interest and reconstructed with 3-mm slice thickness. It is paramount in this case that the patient can tolerate a prolonged prone position. Once access is obtained, a nephrostomy tube can be left *in situ* for subsequent access and the tract can be dilated as described above under general anesthesia.

The stone-free rate post PCNL in the treatment of renal calculi in horseshoe kidneys is similar to that in normal kidneys at 80%. The complication rates reported are also comparable with those of normal renal PCNL: minor complications such as hematuria and infection in 15%, and major complications such as hydropneumothorax requiring insertion of a chest drain in 2% [19].

Ureteroscopy

Retrograde digital flexible ureteroscopy is becoming a more frequently used modality, especially for stones less than 15 mm in diameter using the holmium laser for stone disintegration. However, reported case numbers are small and retrospective, and there may be issues relating to ureteric access requiring prestenting. These cases will generally require use of an access sheath and postoperative stent insertion. To date, such cases have generally been managed in specialist stone centers that can offer the full range of a stone management service [20].

CHAPTER 62

Associated Conditions and Treatment of the Pelvic Kidney

Nadya M. Cinman, Zeph Okeke & Arthur D. Smith
Smith Institute for Urology, North Shore – Long Island Jewish Health System, New Hyde Park, NY, USA

Introduction

The incidence of a pelvic kidney is estimated to be between 1 in 2200 and 1 in 3000 [1]. Given the rarity of a pelvic kidney, it often is an unsuspected finding in patients presenting with vague or atypical abdominal symptoms. Only on further evaluation with radiographic examination is an ectopic kidney identified as the cause [2].

Because of structural and architectural anomalies that can accompany a pelvic kidney, conditions such as chronic obstruction and nephrolithiasis are common. The variation in anatomy of a pelvic kidney creates anomalous vascular patterns and altered spatial relations with adjacent pelvic organs. Therefore, it is important for the urologist to consider ectopic kidney as part of the differential diagnosis in patients with abdominal or pelvic pain and to be familiar with the appropriate work-up and treatment of common associated conditions. This chapter reviews the diseases associated with pelvic kidneys, in particular calculus disease and ureteropelvic junction obstruction (UPJO), and discusses the management options.

Renal development

During weeks 6 and 9 of human development, the kidney ascends from a pelvic position to the lumbar region in a site just inferior to the adrenal glands. Simultaneous with ascent, the kidney rotates medially on its long axis. As the kidney migrates cephalad, the vasculature supplying the organ arises from successive transient aortic offshoots. Blood vessels that are no longer able to reach the migrating kidney will degenerate.

If there is incomplete renal ascent, the kidney will reside in an ectopic position. If the kidney does not ascend at all, it will remain in the pelvis and is referred to as a pelvic kidney. A pelvic kidney lies posterior to the peritoneum, anterior to the sacrum, and caudal to the aortic bifurcation. As a consequence of failure to ascend, the pelvic kidney remains unrotated and often preserves its fetal blood supply from the iliac vessels or the distal aorta [3] (Figure 62.1).

The reasons for failure of the renal ascent from the pelvis have not been well elucidated. Hypotheses include abnormalities of the ureteral bud and metanephric blastema, genetic variants, teratogenic effects, and anomalous vasculature physically blocking ascent [4]. It has been suggested, though, that the initial blood supply to the kidney does not affect its movement to a final position and therefore is unlikely to be the cause of an ectopic position [3].

Nephrolithiasis

The ectopic kidney is thought to be no more susceptible to disease than the normally positioned kidney, except for the presence of calculi and hydronephrosis [3]. A horseshoe kidney has a 20% reported incidence of associated calculi; however, the incidence of stones in pelvic kidneys has not been established [5]. Urinary calculi

Smith's Textbook of Endourology, Third Edition. Edited by Arthur D. Smith, Gopal H. Badlani, Glenn M. Preminger, Louis R. Kavoussi.

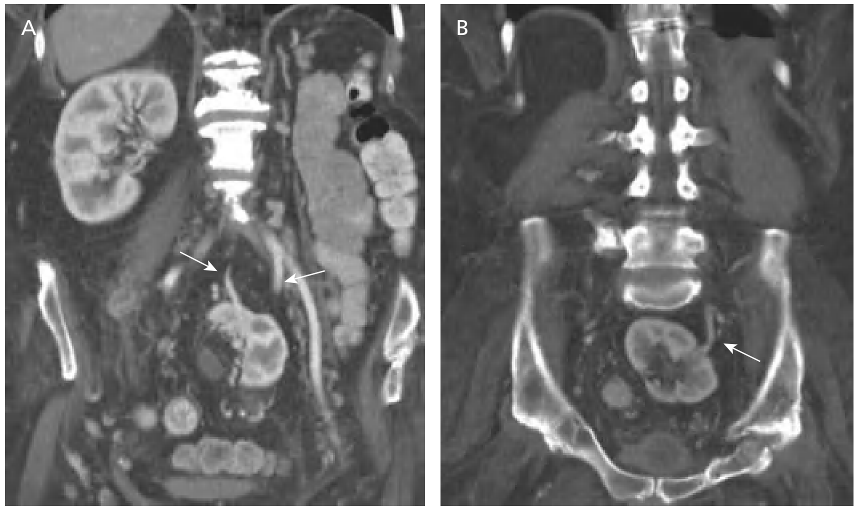

Figure 62.1 (A, B) CT scan of left pelvic kidney demonstrating aberrant vasculature (arrows).

commonly occur in association with urinary stasis or infection in patients with upper urinary tract abnormalities [6]. While renal calculi in horseshoe kidneys have demonstrated metabolic abnormalities predisposing to stone formation, such as hypovolemia, hypercalcuria, and hypocitraturia, no available studies have specifically analyzed metabolic abnormalities in renal calculi of pelvic kidneys [5].

It is the anterior position of the renal pelvis, malrotation of the kidney, high insertion of the ureter, anomalous renal vasculature, or a combination of these factors that can impair the drainage of urine and partially obstruct the pelvic kidney. Although the pelvic kidney is situated in the retroperitoneum, loops of bowel lie between the anterior abdominal wall and the kidney. The pelvic kidney also is more protected by the bony pelvis, with less potential space for maneuverability (Figure 62.2). Because of the greater risk of injuring aberrant vessels or overlying abdominal viscera and nerves, the pelvic kidney presents additional treatment challenges for the urologist. Therefore, alternative approaches to treating nephrolithiasis in the pelvic kidney may yield better outcomes than standard approaches to anatomically normal kidneys.

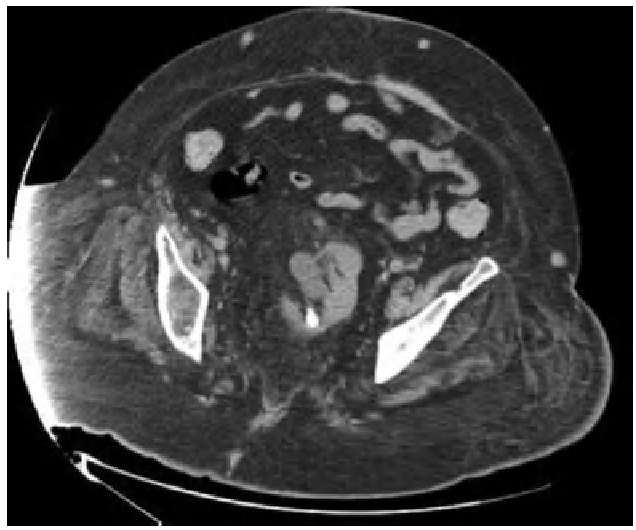

Figure 62.2 Calculus within pelvic kidney seen on CT scan.

Extracorporeal shock-wave lithotripsy

While extracorporeal shock-wave lithotripsy (ESWL) remains a treatment option for stones in anatomically variant kidneys, there are only limited single-institution reports of its use in pelvic kidneys. Renal calculi pose significant technical challenges for nonsurgical treatment modalities such as ESWL, as the kidney is guarded by the bony pelvis and often has surrounding fibrous bands that impair pyeloureteral motility [7]. Demirkensen *et al*. published their series comparing ESWL outcomes in normal versus abnormal urinary tracts [8]. Renal calculi situated under the pelvic brim were treated in the prone position, whereas stones above the pelvic brim were treated in the supine position. Of the eight pelvic kidneys, 38% were stone free 12 weeks after ESWL, 50% had nonobstructive and noninfectious clinically insignificant residual fragments (CIRF) of 4 mm or smaller, and 13% (one patient) failed ESWL. Failure is defined as no fragmentation after three sessions. The pelvic kidney that failed ESWL contained a staghorn calculus. Overall success rates of ESWL (defined as % stone free + % CIRF) for normal and upper urinary tracts were 96% and 93%, respectively ($P > .05$). Normal kidneys did have higher stone-free rates than abnormal kidneys (78% vs 56%), whereas abnormal kidneys had a higher rate of CIRF (37% vs 18.5%). The cause of higher

rates of residual fragments in abnormal kidneys is hypothesized to be a result of abnormal drainage patterns in anatomically variant kidneys, including pelvic kidneys. Therefore larger stones should be considered for alternative treatment options.

Other groups have also reported success with ESWL for stones in ectopic kidneys with clearance rates exceeding 75% for stones with a mean stone burden of 1.4 mL [9]. While many publications state ESWL may be considered as first-line treatment for stones in anomalous kidneys without major complications, the vast majority of the renal anomalies are horseshoe kidneys, malrotated kidneys, or crossed fused ectopic kidneys, with rare cases of pelvic kidneys [10].

However, Talic refuted the notion that abnormal drainage in pelvic kidneys reduces success rates of ESWL, reporting the largest single-institution study to date of ESWL for stones in pelvic kidneys [11]. Talic's series reported a 100% success rate (82% stone free, 12% CIRF) in 14 stone-bearing pelvic kidneys at 3 month follow-up. The high success rate was attributed to appropriate patient positioning during treatment and accurate stone localization. Most of these patients were treated with ESWL in the prone position, permitting anterior entry of shock waves. Additionally stones that were projected over the sacroiliac joint had ureteral catheter placement to aid in the fluoroscopic localization of the stone. Five of the 14 patients required more than one session of ESWL to obtain the reported results.

Some authors claim that even though ESWL can be used for treatment of horseshoe and malrotated kidneys, it is not successful for the majority of stones in pelvic kidneys [12]. Although ESWL does demonstrate satisfactory fragmentation of stones in both normal and abnormal kidneys, abnormal kidneys have higher rates of residual fragments secondary to poorer rates of stone clearance. Residual fragments promote stone recurrence and stone growth and act as a nidus for infection, so patients with stones in ectopic kidneys treated with ESWL warrant close follow-up [13].

Ureteroscopy

The endourologic management of stones in pelvic kidneys presents unique challenges not encountered in normally positioned kidneys. The tortuous ureter often associated with a pelvic kidney hinders deflection of the flexible ureteroscope, potentially limiting access. If the trajectory to the renal pelvis requires greater than two turns of the ureteroscope before it reaches the final calyx, ureteroscopy is limited by the mechanical capacity of the ureteroscope to deflect. There are, however, select reports of successful ureteroscopic stone treatment in pelvic kidneys. Weizer *et al.* noted that with the development of holmium laser lithotripsy, actively deflectable, small caliber flexible ureteroscopes, nitinol baskets, and graspers, retrograde access to calculi in pelvic kidneys can be successful [14]. Their series, one of the largest single-center publications to date, included four patients with symptomatic calculi in pelvic kidneys who failed ESWL. Using a 7.5F flexible ureteroscope, a 200-µm holmium laser fiber, nitinol graspers and baskets, and ureteral stent placement, three patients were rendered stone free, confirmed by plain film or noncontrast computed tomography (CT) scan at 2-month follow-up. Of note, the one failure occurred in a patient who had a 6-mm residual fragment from an original stone burden of 1.5 cm. In another series of four patients with a pelvic kidney treated ureteroscopically for large obstructing stones (>3-cm diameter), three patients were successfully treated with holmium laser lithotripsy, defined as stone free at 3-month follow-up [15]. Holmium:YAG laser lithotripsy was performed in a retrograde manner using energy ranging from 1 to 1.5 J/pulse, frequency ranging from 15 to 20 Hz, and with a mean operative time of 120 min (100–180 min). In cases of anomalous kidneys associated with tortuous ureters, placement of a ureteral access sheath may straighten the ureter, thereby facilitating access to the renal pelvis. The access sheath offers the additional benefit of keeping the ureteroscope straight, which improves deflectability within the renal pelvis.

In patients with a large body habitus, uncontrolled hypertension, altered renal anatomy, or coagulopathy, ESWL efficacy may be limited, lending additional support to a ureteroscopic approach [16]. Likewise, in patients with significant cardiopulmonary disease who may not tolerate prone positioning for percutaneous nephrolithotomy (PCNL) or in patients with coagulopathies who are at risk for hemorrhage, ureteroscopy may constitute a reasonable alternative. Although ureteroscopy has been successful for stones in pelvic kidneys, additional approaches may be necessary for complete fragment clearance.

Laparoscopic nephrolithotomy

Laparoscopy-guided treatment of stones in pelvic kidneys permits visual exposure of the kidney, enhancing safe puncture and correct tract placement integral to PCNL. Laparoscopic-assisted PCNL for the treatment of stones in a pelvic kidney was first described by Eshghi *et al.* [17]. A staghorn calculus was removed using percutaneous techniques under the guidance of the laparoscope, which permitted bowel displacement. In 1992, a case series with an additional two patients was published [18]. One of the patients had a complete staghorn calculus in the pelvic kidney. Since nephroscopic examination only permitted access to parts of the stone, complete stone clearance would have required multiple tract

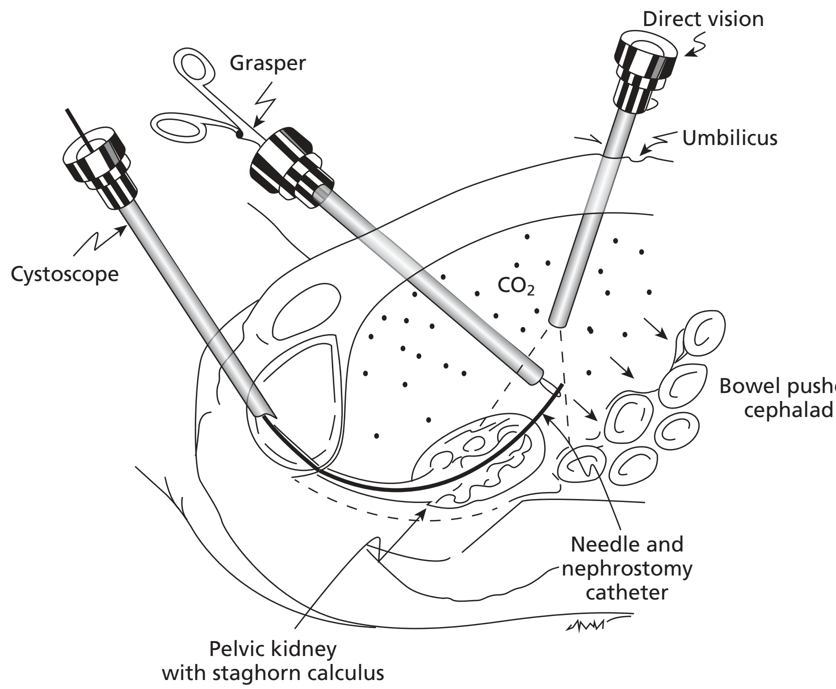

Figure 62.3 Percutaneous access to the pelvic kidney using combined retrograde and laparoscopic techniques (adapted from Lee and Smith [18], with permission).

dilations. The patient then underwent a successful open pyelolithtomy with multiple nephrotomies.

The technique of retrograde nephroscopy being utilized along with laparoscopy to assist percutaneous access permits continuous visual control and facilitates displacement of overlying bowel. Laparoscopy-assisted anterior retrograde percutaneous nephroscopy involves retrograde percutaneous access using a Hunter–Hawkins retrograde nephrostomy needle with adjunctive laparoscopy to manipulate overlying bowel [19] (Figure 62.3). Following fluoroscopic guidewire placement and insertion of a sheathed catheter into the desired calyx, the curved tip Hunter–Hawkins needle is advanced through the middle of the papilla. The needle is then grasped under laparoscopic vision as it is pushed through and exits the surface of the renal parenchyma. The needle is then pulled through the anterior abdominal port along with the guidewire and catheter. A larger catheter is advanced over the first catheter, and the Hunter–Hawkins needle and "rocket" guidewire are removed. This leaves a tract extending from the urethral meatus to the anterior abdominal wall. Using fluoroscopic guidance, the tract can be dilated and the kidney stones removed through a combination of ultrasonic lithotripsy and mechanical extraction. A nephroureteral stent is placed, and a nephrostogram confirms placement of the distal end in the ureter and the portion with holes in the renal pelvis.

Similar reports of transperitoneal laparoscopic access have since been published. Holman and Toth described 15 patients treated with laparoscopy-assisted percutaneous transperitoneal surgery in the Trendelenburg position to facilitate displacement of bowel away from the pelvic kidney [20]. In 1996, Zafar and Lingeman modified the laparoscopic technique of PCNL with the addition of intracorporeal suturing of the nephrostomy site and placement of a ureteral stent, thereby eliminating the need for a transperitoneal nephrostomy tube [1].

In 2002, Troxel *et al.* described an extraperitoneal laparoscopy-assisted percutaneous technique to access the lower pole calyx of a pelvic kidney [21]. These authors cautioned that a transperitoneal approach to the pelvic kidney adds unnecessary risk and morbidity because of the potential for injury to the bowel and violation of the natural peritoneal barrier. This could result in hemorrhage, peritoneal urine leak, peritonitis, or postoperative ileus. Extraperitoneal access to the pelvic kidney reduces the risk of intestinal injury and leaves the peritoneal cavity intact. It has the added benefit of reduced fluid drainage compared with transperitoneal access, and may be a better procedure for patients who have had prior abdominal surgeries with resulting adhesions.

Both anterior and posterior approaches to laparoscopic PCNL in the pelvic kidney have been reported. In 1993, Toth *et al.* described removal of two stones from a pelvic kidney via an anterior transperitoneal approach in which the anterior surface of the kidney was exposed by laparoscopic mobilization of the overlapping sigmoid colon [22]. Puncture of the desired calyx in the pelvic

kidney was performed in an antegrade fashion, using both fluoroscopic and laparoscopic control. In their series of three patients, Mousavi-Bahar *et al*. recommended that before starting dilation of the nephrostomy tract, gas pressure should be decreased to reduce the distance between the skin and the renal system. This makes it possible to easily reach the whole collecting system [23].

In 1993, Goel *et al.* described a variation of the anterior approach in which the tract to the pelvic kidney was established transabdominally and advanced transmesenterically between major mesenteric vessels to permit exposure of the kidney [24]. The proposed benefit of transmesenteric access is a reduced risk of bowel injury associated with bowel manipulation and mobilization. An anterior approach to laparoscopic PCNL for pelvic kidneys may be better suited to patients with a slender body habitus, in whom there is less mesenteric fat, as this may lead to better visibility of the mesenteric vessels and a potentially lower risk of vascular injury.

A posterior approach to laparoscopic PCNL for a pelvic kidney was described by Monga *et al*., who removed a calcified stent from a pelvic kidney via a prone suprailiac approach [25]. A posterior approach to laparoscopic PCNL is not indicated if the pelvicalyceal system is not completely overlapped by the sacrum and its alae. A posterior approach is less advantageous in an obese patient, in whom the transgluteal distance to the pelvic kidney is likely to be greater than with a standard flank incision.

In patients with a complicated history of abdominal procedures or those in whom solid viscera or bone is obstructing optimal renal access, laparoscopy-assisted PCNL may permit improved access. Transhepatic laparoscopy-assisted PCNL and transiliac laparoscopy-assisted PCNL via an iatrogenically created defect in the ileum have been described [26].

Commonly reported complications of PCNL include fever, bleeding, infection, clot colic, catheter dislodgment, and urinary extravasation. A case of incomplete femoral neuropathy has been reported, probably as a result of direct traumatic injury to the dorsal columns of the lumbar plexus [25]. With more medial posterior approaches adjacent to the paraspinal muscles, inadequate length of the nephroscope may inhibit intrarenal manipulation. Additionally, a more medial posterior approach that creates a tract adjacent to the paraspinal muscles and alongside the quadratus lumborum or psoas major muscles places several nerves at risk for injury. The iliohypogastric and ilioinguinal nerves lie anterior to the quadratus lumborum, the genitofemoral nerve lies anterior to the psoas major, and the femoral nerve lies lateral to the psoas major muscle. Consequently, with the anomalous location of an ectopic kidney, meticulous attention must be paid to understanding the specific anatomy in order to reduce the risk of injury to structures that lie along the access tract. Monga's group stressed the importance of conveying to patients the potential for nerve damage during a percutaneous approach to the ectopic kidney.

Desai and Jasani reported the use of ultrasound guidance rather than fluoroscopy for PCNL in 15 patients with ectopic kidneys [27]. Ultrasound guidance can help depict viscera, and the ultrasound probe itself can be used to deflect bowel away from the kidney. However, ultrasound-guided PCNL may be associated with a risk of injury to overlying collapsed bowel, which may not be adequately visible with ultrasound. Additionally, ultrasound-guided PCNL is inferior to a laparoscopy-guided PCNL in the event a second tract is necessary. The endoscopic vision provided by laparoscopy can permit a safer transmesenteric puncture and tract dilation compared with ultrasound imaging, which provides less clarity and cannot facilitate creation of an additional tract [21].

Laparoscopy as an adjunctive tool in the endoscopic treatment of difficult stones has yielded stone-free rates between 91% and 100% in the few available case series. Gupta *et al*. reported a 100% stone-free rate in a cohort of four patients with pelvic kidneys who underwent laparoscopy-assisted PCNL [28]. Two of these patients had failed prior ESWL. The mean stone size was 2.1 cm. The upper calyx was accessed in all four cases, with three stones in the renal pelvis and one in a calyx. Matlaga *et al*. reported a series of laparoscopy-assisted PCNL in eight patients with a 100% stone-free rate. These patients were left "tubeless," without external drainage nephrostomy tubes, and instead had internal double-J ureteral stent placement [26].

Laparoscopic pyelolithotomy

In 1996, Harmon *et al*. reported laparoscopic pyelolithotomy in a patient with a pelvic kidney who had undergone two unsuccessful attempts at ESWL and one failed ureteroscopy [29]. Given the prior treatments, adhesions were dense and visibility was poor. Laparoscopy was useful in permitting direct viewing of aberrant vessels and peripelvic inflammation. Once the pelvic kidney was dissected and exposed appropriately, a 2-cm pyelotomy was created, and the calculi were extracted with grasping forceps. The depth and location of the pyelotomy made it difficult to perform endoscopic or suture closure, so the renal pelvis was left open. When the renal pelvis was not easily visible, the ureter was identified, traced proximally to the renal pelvis, and isolated with a vessel loop. Because the stones were large and solitary, the vessel loop was used for traction and identification rather than prevention of stone migration [30]. Presence of a ureteral catheter permits flushing to clear residual

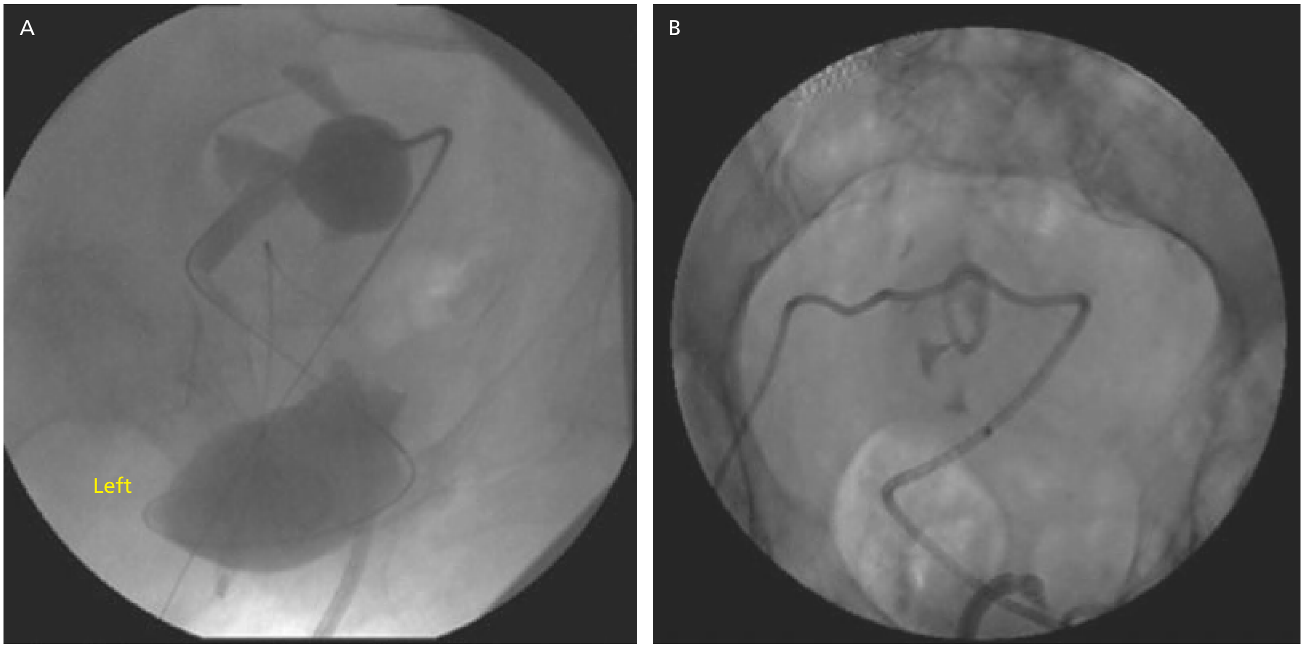

Figure 62.4 Guidewire and nephroureteral stent placement demonstrating ureteral tortuosity in a pelvic kidney. Percutaneous access was gained via the transgluteal approach via the greater sciatic foramen. (A) Lateral view with a guidewire, and a Foley catheter in bladder. (B) Anteroposterior view with a nephroureteral stent in place and a Foley catheter in bladder.

fragments, and a flexible cystoscope or ureteroscope permits identification of hidden calculi. Ideally, the pyelotomy is closed with sutures. However, if this is not possible because of its location, an internal double-J stent should be placed along with a bladder catheter for 2 weeks to promote closure of the pyelotomy. A suction drain is positioned in the perinephric area through a working port to prevent urine leak [31].

Laparoscopic pyelolithotomy in a pelvic kidney has been cited as an approach that is well suited for accessing anteriorly or laterally displaced renal pelvises in ectopic kidneys [32–34]. A laparoscopic transmesocolic pyelolithotomy, if feasible, is an option that avoids colon mobilization [35]. Intraoperative fluoroscopy permits identification of the renal pelvic and allows for periodic re-evaluation of pending stone burden. With improvement in laparoscopic suturing techniques and laparoscopic suturing devices, pyelotomies are sutured closed in a running fashion.

In a small series comparing laparoscopy-assisted PCNL versus laparoscopic pyelolithotomy, laparoscopic pyelolithotomy is reported as the ideal treatment for large renal pelvic stones in ectopic kidneys because it has the advantage of avoiding renal parenchymal puncture [1]. However, the number of published cases for laparoscopic pyelolithotomy is small, with the need for intracorporeal suturing making it a more technically challenging procedure. Therefore, the mean operative time for laparoscopic pyelolithotomy (n = 6) was longer than for laparoscopy-assisted PCNL (n = 5) in the present study (mean operative time 141 min vs 183 min, respectively, $P = .01$) [36].

Transgluteal percutaneous nephrolithotomy

An alternative posterior approach to laparoscopic PCNL was described by Watterson *et al*. who fluoroscopically accessed the pelvic kidney via the greater sciatic foramen [37]. After CT evaluation and analysis to optimize tract placement, fluoroscopic guidance was used to establish the tract, thereby avoiding injury to nearby bowel loops or blood vessels. Following interventional radiologic principles of deep pelvic abscess drainage, the approach through the greater sciatic foramen rendered the patient stone free with an uncomplicated postoperative course. Recommendation is to place the tract as close to the sacrum as possible to avoid vascular or neurologic structures. More recently, at our institution we performed percutaneous stone extraction in a pelvic kidney via the greater sciatic foramen (Figure 62.4). The patient had an uncomplicated hospital course and remained stone free on follow-up imaging (unpublished observations).

Ureteropelvic junction obstruction

UPJO is associated with some renal anomalies and has been reported to occur in 22–37% of ectopic kidneys [38]. Endoscopic incision of the UPJ for relief of obstruction has been used since the early 1980s [39]. UPJO in a

congenital pelvic kidney presents additional treatment difficulties beyond those of anatomically normal kidneys because of variations in vasculature and altered spatial relations with surrounding organs as a result of malrotation and the kidney's anomalous location.

Percutaneous endopyelotomy

To date, there have been few reports addressing the treatment of UPJO in patients with congenital renal anomalies, with exceedingly rare reports of the treatment of UPJO in a pelvic kidney. Salas *et al*. performed percutaneous endopyelotomy in six patients with horseshoe kidneys [40]. In 1998, Jabbour *et al*. reported a series of antegrade endopyelotomy in ectopic kidneys using a laparoscopy-assisted approach with a Hunter–Hawkins catheter to obtain access for the antegrade percutaneous incision. Their series, which included two pelvic kidneys, reported a 78% success rate for the treatment of UPJO in congenitally abnormal kidneys [41]. Most of the published endopyelotomy series have involved an antegrade percutaneous approach, with some additional reports utilizing a retrograde ureteroscopic technique. A tapered endopyelotomy stent traversing the UPJ is recommended for 6 weeks [41, 42] (Figure 62.5). Oppenheimer and Hinman determined that 6 weeks of stenting was needed for regeneration of the muscular wall of the ureter [43]. An excretory urogram 1 month after stent removal is recommended to assess the patency of the UPJ. The advantages of endopyelotomy over open surgical repair include a shorter hospital stay and faster return to routine daily activities.

Figure 62.5 Nephroureteral stent placed after percutaneous endopyelotomy in a pelvic kidney.

Laparoscopic pyeloplasty

In 2004, Bove *et al*. reported three cases of laparoscopic pyeloplasty in pelvic kidneys with UPJO [44]. The laparoscopic approach provided good surgical exposure, and operative times were comparable to those of laparoscopic pyeloplasty in anatomically normal kidneys. The authors commented that laparoscopic pyelolithotomy can be performed concomitant with pyeloplasty when kidney stones are present.

Ureteroscopy

Although a percutaneous approach to the treatment of UPJO in the ectopic kidney is feasible, there is a risk of bleeding from injury to anomalous blood vessels or adjacent pelvic organs. Bales *et al.* suggest that ureteroscopic access may be advantageous in patients with a pelvic kidney, as it avoids percutaneous access [45]. Preoperative radiographic evaluation to determine the anatomy of the major vessels (angiography) and the location of surrounding organs is recommended, and intraoperative endoluminal ultrasonography may serve as a useful adjunct [46].

There are limitations to the ureteroscopic approach to UPJO in pelvic kidneys. Baba *et al*. employed a percutaneous approach in a patient with a pelvic kidney, UPJO, and a concomitant ureteral calculus [47]. Percutaneous transperitoneal endopyelotomy and transluminal antegrade ureteroplasty after ultrasonic lithotripsy were performed under laparoscopic guidance. A preoperative CT scan revealed tortuosity of the ureter with lateral rotation of the pelvic kidney and a dilated extrarenal pelvis. Preoperative pelvic angiography revealed hyperrotation (270°) of the pelvic kidney, with the main vascular pedicle passing dorsal to the kidney to reach the renal hilum. An attempt at ureteroscopy was aborted because of failure to pass the ureteroscope beyond the impacted stone. The stone was treated with ultrasound lithotripsy and forceps removal of the remaining fragments. After creation of the nephrostomy tract, a flexible nephroscope was used to inspect the narrowed UPJ, and a ureterotome was advanced over the working guidewire to incise the anterior wall of the obstruction. Serial twists of the ureter can occur in association with an ectopic kidney as a result of hyperrotation of the ureter. This rare situation creates a technical challenge in accessing pelvic kidneys and limits the utility of ureteroscopy in managing disease.

In a case report by Simone *et al*, one patient with a UPJO in a pelvic kidney underwent a laparoscopic endopyelotomy to treat the short obstructed ureter by tubularizing the redundant renal pelvis to create a neoureter. At 6-month postoperative follow-up, the

patient remained with resolved hydronephrosis and demonstrated good renal function [48].

Laparoscopic pyelovesicostomy

Laparoscopic pyelovesicostomy was described by Davis and Wolf [49]. Following dissection of the prevesical space, a cystotomy was made equal to the length of the incision in the medial aspect of the dilated right renal pelvis. The vesicostomy was then sutured to the pyelotomy with a running absorbable suture. Pyelovesicostomy has been described as a management option for ureteral obstruction since 1973, but laparoscopic pyelovesicostomy is a recent approach [50]. Although there are advantages such as the relative technical ease with a short operative time and reduced blood loss, the disadvantages include a risk of bacterial cystitis progressing to pyelonephritis and the discomfort associated with a full bladder [47].

Extrarenal calyces are an uncommon congenital anomaly that may accompany ectopic kidney [51]. Extrarenal calyces can be associated with UPJO, with reports of obstruction in 22–37% of patients. In 2006, Wadhwa *et al*. described a unique laparoscopic approach to UPJO in a pelvic kidney associated with extrarenal calyces [52]. A window was created in the mesocolon to allow viewing of and access to the renal pelvis and the junction of the extrarenal calyces with the ureter. After dismembered pelvic reduction, the mesocolic incision was closed. This approach reportedly permitted excellent exposure of the anomalous renal anatomy and avoided the need to mobilize and translocate the sigmoid colon.

Conclusions

Although ectopic renal anomalies are not an infrequent finding, pelvic kidneys specifically are regarded as rare. While kidney stones and UPJO can be treated by minimally invasive techniques, the pelvic kidney requires additional treatment considerations because of the spatial orientation of the pelvis and the relation to surrounding organs, vessels, nerves, and bones. Stones in pelvic kidneys can be treated by ESWL, albeit with a greater need for retreatment or secondary procedures. Laparoscopy-guided percutaneous approaches also are effective in treating stones in a pelvic kidney and provide a safe means of establishing the tract. Given the altered and sometimes tortuous nature of the ureter in a pelvic kidney, ureteroscopy may have a limited role because of difficulty in passing instruments into the kidney. Ureteroscopic treatment of UPJO may be limited for the same reasons, and better results have been obtained with percutaneous endoscopic intervention. To date, multi-institutional large cohort studies involving comparative treatment of diseases in pelvic kidneys have been limited by the rarity of the anomaly. Additional studies are needed to compare the various treatments for disease of the pelvic kidney in order to decide which options have the most beneficial outcomes.

CHAPTER 63

Management of Stone Disease in Renal Transplant Kidneys

Ali Rıza Kural[1] & Can Öbek[2]

[2]Department of Urology, Cerrahpasa School of Medicine, University of Istanbul, Istanbul, Turkey

Introduction

Renal transplantation remains the optimal treatment for patients with endstage renal disease. It offers a longer survival and a better quality of life compared to dialysis. With the advances in immunosuppression and national transplant programs in many countries, including laparoscopic and hand-assisted laparoscopic surgery, renal transplantation is becoming increasingly common. The resulting improvement in graft and patient survival has led to the frequent presentation of the less common and the longer-term complications of transplantation. One such complication is urolithiasis in renal transplant patients. The incidence has been reported to be around 1% in successful transplants (range 0.3–3% in our review), and it is likely to increase as more transplants are performed and graft survival is prolonged [1, 2].

A calculus in a grafted kidney may develop *de novo* after transplantation, or may pre-exist in the allograft before transplantation, which is usually referred to as donor graft nephrolithiasis. There are various risk factors associated with transplantation patients that can lead to stone development, including metabolic disorders, infection, urinary stasis, and foreign body nidus. Some reports have suggested women outnumber men with this clinical entity [3, 4]. Stone disease puts transplant patients at greater risk for urinary tract obstruction, renal failure, and infection compared to the risk in the general population. Therefore, early diagnosis and proper management are essential for a successful outcome.

Historical perspective

One of the earliest reports of post-transplant urolithiasis was that of Hume *et al*. in 1966, who reported on a patient with a staghorn calculus associated with hyperthyroidism [5]. The stone regressed slightly after parathyroidectomy. Urolithiasis in graft kidneys has since been recognized as a complication of kidney transplantation. Dominguez *et al*. in 1970 reported on the occurrence of calcium phosphate stones in a renal allograft 2 months after transplantation. A parathyroid adenoma was noted and removed at the exploration of the neck [6]. In the same year, Latimer *et al*. reported calcium phosphate stones in the pelvis of a renal allograft 4 months after transplantation [7]. Their patient had both hyperparathyroidism and urinary tract infection (UTI) secondary to a ureterovesico-cutaneous fistula. There was no stone recurrence following parathyroidectomy and fistula repair. One year later, the development of nephrocalcinosis in renal transplants due to hypercalcemia and hyperparathyroidism was recorded with changes being observed microscopically as early as 4 weeks after transplantation [8]. Rosenberg *et al*. reported in 1975 on a patient who developed stones in the renal pelvis 4 months after transplantation [9]. Three major predisposing factors of nephrolithiasis found in the patient were hyperparathyroidism, UTI, and renal tubular acidosis. Parathyroidectomy was performed; however, surgical therapy for nephrolithiasis was deferred. In due course, she developed 17 "rejection

Smith's Textbook of Endourology, Third Edition. Edited by Arthur D. Smith, Gopal H. Badlani, Glenn M. Preminger, Louis R. Kavoussi.

episodes" with fever and serum creatinine elevations, and finally died from a febrile attack. With current knowledge, we believe that it would not be incorrect to assume that at least some of her "rejection" episodes were actually septic episodes associated with the underlying stone disease.

The initial report on donor graft lithiasis was made by Lerut *et al.* in 1979 [10]. They reported on a female patient who developed ureterohydronephrosis secondary to distal ureteral stenosis and an unsuspected calculus in an inferior calyx of the donor kidney. The ureter was reimplanted and a pyelolithotomy performed. More than 30 years ago these authors underlined the importance of inspection of the transplanted kidney to exclude the presence of a graft calculus. A second case of donor graft lithiasis was reported in 1984 [11]. The patient was diagnosed as having acute graft rejection until a stone causing ureteral obstruction was discovered. Bhadauria *et al.* was the first to describe the treatment [shock-wave lithotripsy (SWL)] after transplantation of a stone-bearing kidney [12]. A total of 34 cases of nephrolithiasis in living donor transplants were published up to 2008; 28 were known to harbor stones prior to transplantation [13].

Predisposing factors for stone disease in kidney transplant recipients

Metabolic disease, infection, immunosupression, ureteral obstruction (stricture), chronic urinary stasis (in a relatively horizontally lying kidney), foreign body nidus (nonabsorbable suture material), and donor graft lithiasis are accepted as the most common causes of stone formation complicating a transplantation.

Renal transplant patients who develop stones should undergo a metabolic evaluation to prevent future stone formation. The management of postrenal transplant hypercalcemia and hyperparathyroidism, and the role of parathyroidectomy have been thoroughly discussed in the literature. Parathyroidectomy can lower calcium level by decreasing the filtered load of calcium and by correcting or improving an associated renal tubular acidosis [9]. Steroids are often a part of immunosuppressive treatment, and may cause calcium reabsorption from the bones, resulting in hypercalciuria. Most stones in renal allografts have been reported to be calcium oxalate stones [14, 15]. In half of these patients, immunosupression with cyclosporine can produce hyperuricosuria, which may contribute to stone formation [16]. However, the role of hyperuricosuria and uric acid stone formation remains controversial with a reported incidence of uric acid stones in the range of 0.2–10% [4, 17, 18]. Guitard *et al*. reported a case of sulfadiazine-related obstructive urinary tract stone in a kidney transplant recipient [19]. Glicklich *et al.* reported the first case of 2, 8-dihydroxyadenine urolithiasis in a transplanted kidney [20].

Recurrent UTIs and the production of more concentrated alkaline urine have been held responsible for contributing to calculus formation in transplant patients [3, 18]. Urinary stasis is another factor that may have a role in stone development; a relatively horizontal kidney could potentially be associated with urinary stasis. Voiding dysfunction could also play a role in some patients and needs to be recognized and treated. Stricture at the ureteral anastomosis may ensue after anastomosis.

It has been speculated that the increased glomerular filtration rate and urine output on a per nephron basis that a transplanted kidney experiences may be sufficient to overcome any propensity the kidney may have for subsequent stone formation. However, this theory has not yet been proven [21].

Symptoms and signs

The most common presenting symptoms and signs are fever, septicemia, impairment of renal function, decreased urine output, anuria, and hematuria [3, 15, 22]. Typical renal or ureteral colic pain from acute hydronephrosis secondary to an obstructing stone in the transplant kidney is typically not present due to the severing of perinephric nerves during transplantation. Nevertheless, a minority of patients with a renal transplant report pain due to distention of the overlying fascia secondary to an enlarged, obstructed kidney [14, 23]. The presence of a stone in a transplant patient may cause a clinical presentation that may be easily mistaken for an acute rejection or acute tubular necrosis [11]. Delay in proper diagnosis may lead to loss of the graft; hence, intervention is warranted in most transplant patients who are found to have a stone [22]. Consequently, any patient presenting with unexplained fever and signs of graft rejection should be investigated with ultrasonography and noncontrast-enhanced computed tomography (CT) to exclude renal calculi [24] (Figure 63.1).

Stone disease as an inclusion/exclusion criteria for kidney donation

Kidney donation is a unique situation in which the individual undergoing the procedure has the potential for harm with no physical benefit [25]. Thus, it poses an ethical dilemma of how much risk is acceptable for a living donor [26]. Due to the organ donor shortage, some transplantation centers have relaxed their acceptance criteria for living kidney donation and allow what have been termed "complex living donors" [26]. Complex living donors are individuals with normal renal function at the time of evaluation who possess

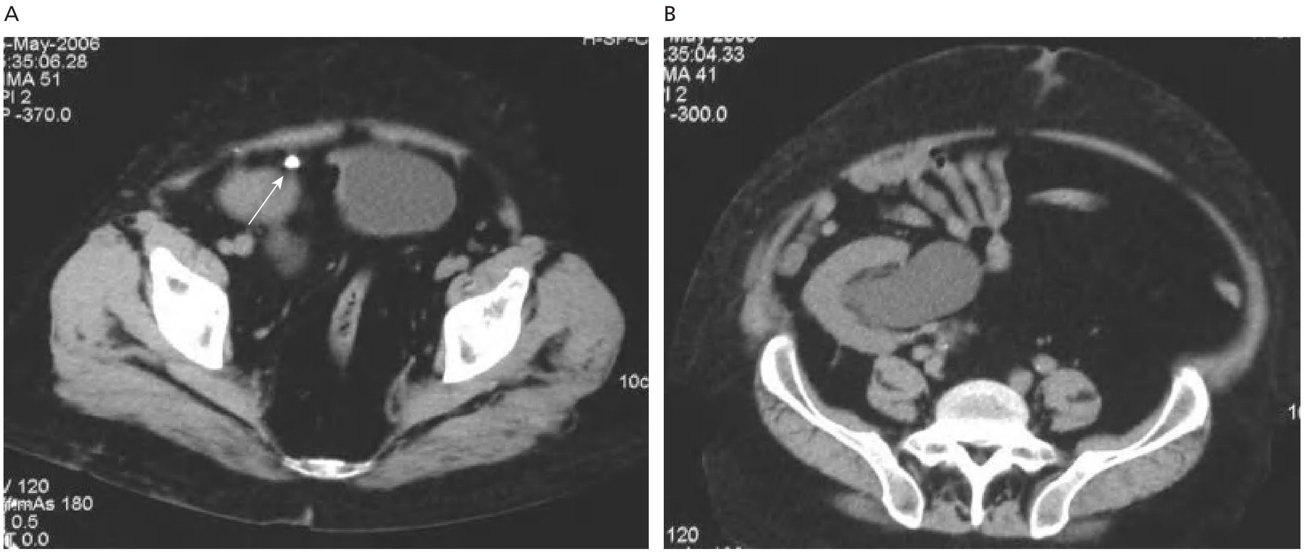

Figure 63.1 (A) CT image of an 8-mm upper ureteral stone in a transplanted kidney (arrow) (courtesy of Nejat Tansu MD). (B) Hydronephrosis due to the ureteral stone in the same patient (courtesy of Nejat Tansu MD).

potential risk factors for kidney disease in the future. A donor with nephrolithiasis is a complex donor [27]. The use of screening CT angiography has lead to an increased incidence of exclusionary radiographic findings in renal transplant donors [28]. Asymptomatic nephrolithiasis is one of the most common reasons for this increased exclusion rate [29].

The guidelines and consensus statements do not necessarily exclude living kidney donation in the context of urolithiasis. The general recommendation is to perform a risk stratification for donor and recipient with respect to stone composition, metabolic evaluation, the presence of single versus multiple stones, and the duration of stone-free episode. The US and UK guidelines consider current nephrolithiasis as a "relative contraindication" for kidney donation [30, 31]. They suggest taking stone composition into account; however, the criteria for inclusion or exclusion are not clear in the US guidelines. In the European Best Practice Guidelines, presence of multiple stones is the sole exclusion criteria irrespective of stone composition [32]. The more recent Amsterdam Consensus Conference states that stone bearers may donate the stone-bearing kidney if metabolic disorders and infections are excluded, and the stone is solitary, less than 1.5 cm in diameter, or potentially removable during transplantation (Table 63.1) [33]. The size threshold of 1.5 cm stems from a consensus decision rather than scientific evidence [33]. *Ex vivo* ureteroscopy (ExURS) during transplantation is suggested as a feasible means of stone treatment for these donors.

The results of a survey conducted in the USA reflect a temporal trend toward increased acceptance of donors

Table 63.1 Potentially suitable donors as recommended by the Amsterdam Consensus Conference on the Living Donor (adapted from Delmonico [33]).

Potentially suitable donors
1. Asymptomatic potential donor with *history of single stone* if:
No hypercalciuria/hyperuricemia/cystinuria/hyperoxaluria
No metabolic acidosis
No urinary tract infection
No multiple stones or nephrocalcinosis (CT scan)
2. Asymptomatic potential donor with *current single stone* if:
Donor meets criteria under 1
Current stone size < 1.5 cm or potentially removable during transplant
Stone formers who should not donate
Nephrocalcinosis on X-ray
Bilateral stone disease
Stone recurrence while on appropriate treatment (failed therapy)
Stone types difficult to prevent/with high recurrence:
Cystine stones
Struvite stones
Stones associated with inherited or other systemic disorders:
Primary or enteric hyperoxaluria/distal renal tubular acidosis/sarcoid
Stones in the setting of inflammatory bowel disease

with a history of kidney stones, both in attitude and in practice [27]. The great majority (77%) of responding centers allowed stone formers to donate. More than one-third (37%) of centers reported a change in their attitude towards accepting donors with a history of kidney stones over the last 5–10 years or with current stones. There is no formal donor registry in the USA following stone-bearing donors over time [34]. History of or present urolithiasis in a potential kidney donor requires a thorough work-up, as suggested by international guidelines, since stone disease may recur both in the transplant and in the remnant donor kidney [35]. The highly sensitive CT screening of kidney donors and the acceptance of donor candidates with incidental stones merit the analysis of stone-related complications in donors and recipients. In the absence of data, physician practices are probably based on trends of need rather than published patient outcomes or evidence-based guidelines [27].

While the Amsterdam Consensus Statement and the European Best Practice Guidelines do not make any recommendations regarding the necessity of a stone-free episode, the UK and the US guidelines advocate a 10-year stone-free period prior to kidney donation [30, 31, 33, 35]. In a survey conducted in Germany, only one center was in favor of complying with the 10-year rule [13]. In their evaluation of this survey, Giessing *et al*. proposed a 2-year stone-free period to be satisfactory if metabolic and infectious disorders were excluded [13].

Identification and exclusion of a metabolic or infectious stone disease and stone composition are at least as important as stone size. Nevertheless, the obstacles associated with identifying stone composition without removing the stone are well-known to all urologists. The Amsterdam Consensus Statement and the UK guidelines exclude donors with a history of cystine and struvite stones, while the US guidelines describe the high recurrence rate of these stones without offering specific recommendations [30, 31, 33]. The European Best Practice Guidelines fail to make any suggestions on the relevance of stone composition [32]. Potential donors with a history of uric acid or calcium phosphate stones and a normal metabolic work-up would not be excluded according to the Amsterdam Consensus Conference [33]. In contrast, the UK guidelines exclude these donors, while the US guidelines fail to make strict recommendations [30, 31]. As for calcium oxalate stones, the Amsterdam Consensus Conference advocates exclusion of these potential donors if the stones are due to a hereditary condition, e.g. primary or enteric hyperoxaluria, distal renal tubular acidosis, or inflammatory bowel disease [33]. The British guidelines mention the high recurrence rate of oxalate stones, suggesting taking caution; but they accept these donors if their metabolic work-up is normal [30].

A survey questioning the attitude to nephrolithiasis in potential living kidney donors in Germany revealed interesting results: Nephrolithiasis at the time of transplantation was an exclusion criterion at 36% of the German centers [13]. A history of stone disease did not preclude living kidney donation. The length of stone-free episode was regarded as relevant by 42% of all centers. Stone composition was a criterion for 54%. Less than half of the centers excluded donors with cystine stones and only two centers excluded donors with struvite nephrolithiasis. Giessing *et al* concluded that the recommendations were mostly disregarded among the surveyed centers, and they speculated that it might suggest a lack of awareness of the risks associated with nephrolithiasis in the context of living donor kidney transplantation [13]. Another similar survey performed in France revealed that half of French kidney transplant centers refuse living kidney donation when the donor has a history of stone disease, even in the absence of present urolithiasis [36].

Management of a "complex donor" with stone disease

The Amsterdam Consensus Statement references only one of eight studies available at the time of its publication [13]. More studies have been published on the retrieval of a stone-bearing kidney and its management before, in the course of, or after transplantation. Bhaduria *et al.* performed SWL after live donor transplantation; Yigit *et al.* treated two donors with SWL prior to donation and performed bench pyelotomy in another prior to transplantation [12, 37]. Rashid *et al.* performed back-table ureteroscopic stone removal [38]. Recurrence of stone disease was not detected in these three series with nearly 3-year follow-up. Devasia *et al.* performed SWL in a living donor with a 12-mm upper calyceal stone before transplantation [39]. Three kidneys were transplanted with known 4-mm stone fragments and all had an uncomplicated course [39]. Kumar *et al.* managed one of six live donors with a pelvic stone with bench pyelolithotomy and the remaining five with SWL after transplantation [40]. In two donors, they removed ureteral stones after kidney retrieval. Recipients remained free of stone recurrence or functional deficit. They reported a complication of obstructive recurrent stone disease development 2 years after transplantation in a patient requiring emergency stenting and ureteroscopic stone extraction.

Klinger *et al*. suggested using ultrasound routinely in the operating room in parallel with transplantation, so that ischemia time would not be influenced [4]. All nine stones in the allografts in their series would have been detected if ultrasonography had been performed. The authors stated that stones diagnosed prior to or during

transplantation can be easily removed during the procedure, and do not jeopardize transplantation results, thus reducing postoperative morbidity and costs. On the other hand, the morbidity of allograft stones diagnosed immediately after transplantation may be high, as renal function is variable; any ureteral obstruction requires immediate intervention. Of the five patients they transplanted with stones, four (80%) developed complications [4]. Three needed an emergency nephrostomy, with one patient having permanent renal impairment and another requiring ureteral reimplantation. Therefore, their conclusion was that treatment of these stones cannot be delayed and immediate stone removal is needed. Capocasale *et al*. suggested not treating calyceal stones at the time of bench surgery due to increased risk of urinary leak from the pyelolithotomy suture line and the availability of less invasive endourologic procedures after transplantation [41]. However, they were in favor of removing ureteral stones.

Ex vivo ureteroscopy

The Amsterdam Consensus Conference suggests ExURS during transplantation as a feasible means of stone treatment for donors with urolithiasis [33]. ExURS may be easier to perform compared to *in vivo* ureteroscopy, since the removed kidney no longer exhibits the normal anatomic narrowing of the ureter at the iliac vessels and the ureterovesical junction [21]. In addition, the kidney can be manipulated to vary the ureteropelvic angle to facilitate access to all calyces. The average additional cold ischemia for the ExURS is below 10 min, well within the period accepted to be safe for subsequent transplantation [21].

Rashid *et al*. reported the largest experience with ExURS during transplantation [21]. Immediately after kidney explantation, the kidney was flushed and prepared for transplantation in the usual fashion, and then placed in sterile, iced preservation solution. Dilation of the ureter was performed in only one case. Ureteroscopy was performed using a 6.9F semi-rigid ureteroscope. The kidney and ureter were kept cold throughout the ExURS by immersion in an iced saline bath. All stones were localized under direct vision in comparison with previous CT, except in the first patient in whom fluoroscopy was used. Stone burden was treated with holmium laser lithotripsy or endoscopic basketing. Upon completion of the ExURS procedure, the kidney was transplanted. A stent was placed at ureteral implantation when deemed necessary to aid passage of stone fragments, or if there were concerns for ureteral trauma and subsequent edema potentially leading to obstruction.

The procedure was not only technically feasible, but also almost uniformly effective in that all but one stone was successfully treated and/or removed, and all kidneys were rendered stone free. Stone recurrence was observed in neither the recipients nor the donors. There were no instances of post-transplant ureteral anastomotic leak or stricture. Care was taken to minimize handling the ureter and the smallest diameter scope available was used. Routine dilation of the ureter was not necessary when using a 6.9F semi-rigid instrument. The semi-rigid ureteroscope was preferred due to its superior optics, shorter length, and subsequent ease of use. Negotiating the scope in all calyces was facilitated by rotating the kidney, so that the desired calyx was in-line with the ureteral axis. A minimal amount of pressure irrigation was used to minimize the potential risk of pyelovenous, pyelotubular, or pyelolymphatic reflux.

In a small series, Triverdi *et al*. reported on two patients managed with ExURS [42]. An 8.5F semi-rigid ureteroscope was used without ureteral dilation. The kidney was cooled throughout the procedure in an iced saline bath, stones were fragmented with pneumatic energy, and fragments were retrieved with forceps. Uretereoneocystostomy was performed over a double-J stent. Renal function was not adversely influenced by the intervention.

Thus, patients who are acceptable kidney donors and harbor incidental, unilateral, nonobstructive nephrolithiasis can safely donate and effectively have the stone burden treated by ExURS with or without holmium laser lithotripsy at transplantation. This method is technically feasible, has no apparent effect on allograft function, and is not compromised by ureteral complications and *de novo* stone formation.

Importantly, a donor with current stone disease must be informed about a potentially increased risk for themselves and the recipient. Donors must realize the importance of careful monitoring and express a commitment to practicing avoidance measures for stone recurrence. Likewise, recipients must be thoroughly informed of the potential for stone-related complications in an allograft with a stone left *in situ*. The recipient must weigh the risk of an obstructing stone that might result in delayed recognition of graft failure against the risk of a shorter lifespan and increased cardiovascular morbidity associated with renal failure without transplantation [29]. Fully informed consent and life-long close follow-up is explicitly advocated only in the UK guidelines, but must be the standard procedure in the context of nephrolithiasis in living kidney donors [13, 30].

Treatment of stone disease in a graft kidney

The treatment of *de novo* stones in transplanted kidneys follows regular stone management guidelines for single kidneys in general. Since transplant patients depend on

their solitary kidney for renal function, calculi should be treated aggressively to minimize the possibility of obstruction and loss of graft function. The management of these patients is complex because of their immunosuppressive status, borderline renal function, and an altered renal innervation that masks the typical presenting symptoms [16]. Management options include close monitoring, SWL, ureteroscopy, percutaneous nephrolithotomy (PCNL), and open surgery when all else fails. There are no data on the laparoscopic treatment of stone disease in grafted kidneys.

Active surveillance

Monitoring renal calculi in the patient with a transplant is not ideal, although in certain situations it can be performed [15, 16, 41]. In patients with small stones of 4 mm or smaller and no signs of impaired allograft function, a watchful waiting approach is justified. The common medications used for metaphylaxis may not be tolerated by transplant patients, e.g. the potassium load from potassium citrate or the sodium load from sodium bicarbonate. Close monitoring with weekly serum creatinine levels and renal ultrasound is mandatory, but has its pitfalls. Renal ultrasonography alone may be unreliable in detecting moderate obstruction, because dilation in the collecting system is not pathognomonic. Moreover, the anatomic variation of the allograft position may overestimate the degree of hydronephrosis. The only definite signs of an arising problem are decreased urine production despite sufficient fluid intake and an increase in serum creatinine. It should always be recognized that since the kidney is denervated, typical pain or renal colic is not to be expected. As with active surveillance in any other disease, compliance of the patient must be excellent for a conservative approach to work.

Shock-wave lithotripsy

SWL is often a reasonable initial treatment for stones smaller than 1.5 cm in diameter [3]. However, there are some limitations for routine utilization of SWL. The overlying bony pelvis might preclude adequate localization of the transplanted kidney and also can cause shock-wave attenuation, decreasing SWL efficacy [14]. Patients are usually treated in the prone position to better visualize the stone. It is often required to place a concurrent percutaneous nephrostomy tube in an acutely ill patient [15] (Figure 63.2). The development of steinstrasse may cause obstruction and risk kidney function.

Some groups have reported success with SWL in this patient cohort [3, 4]. Challacombe *et al*. observed treatment success in 13 patients in whom stones with a mean size of 8.1 mm were treated with SWL [3]. Although

Figure 63.2 Kidney, ureter, and bladder (KUB) image of a patient who was rendered stone free after two shock-wave lithotripsy treatment sessions. A nephrostomy tube was placed in the transplanted kidney due to anuria initially, and was not removed until after treatment (courtesy of Nejat Tansu MD).

seven of the 13 patients required multiple SWL treatments, the investigators concluded that SWL is an acceptable treatment alternative for stones of less than 1.5 cm in the allograft kidney. Others have reported difficulty with SWL localization of the allograft and the stone because of the complex bone structures in the pelvis [12]. The group from the University of Vienna stated that with increasing experience, they would be more restrictive in placing nephrostomy tubes during SWL treatment [4]. They further suggested close monitoring of steinstrasse to be sufficient unless infection and/or oliguria were present and providing the overall stone burden was low.

Ureteroscopy

Retrograde access to a transplanted kidney is typically difficult owing to the anterior location of the ureteral anastomosis and thus, ureteroscopy is not an easy option for stone management in these patients [24]. Nevertheless, it could be an initial option for ureteral stones or performed after failed SWL [22]. It is essential to determine the location of the orifice and whether the distal native ureter was used. Flexible instruments with active secondary deflection are particularly useful in reaching calculi in transplanted kidneys [3].

Percutaneous nephrolithotomy

Renal stone extraction through a percutaneous access was initially reported by Fischer *et al*. in 1982 [43]. They

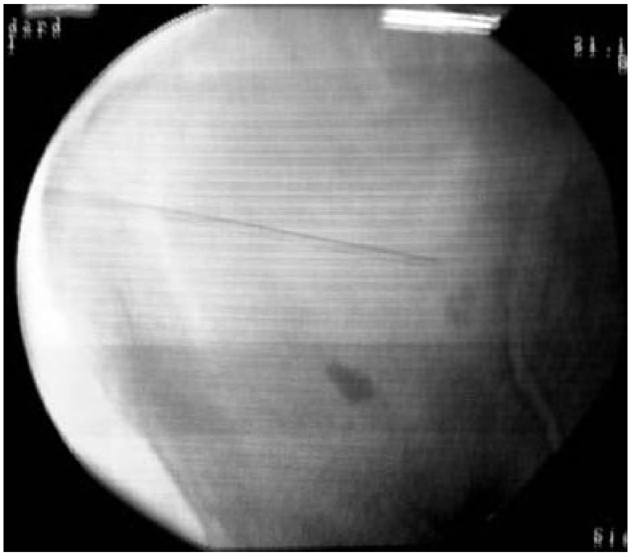

Figure 63.3 Fluoroscopic imaging of two stones in a transplanted kidney. The stones are located in the renal pelvis and lower calyx. The collecting system has been punctured with a Chiba needle (courtesy of Ali Ulvi Onder MD).

Figure 63.4 Percutaneous nephrolithotomy in a patient with a transplanted kidney. The tract is dilated with an Amplatz balloon and an Amplatz sheath is introduced (courtesy of Ali Ulvi Onder MD).

removed a uric acid stone through a nephrostomy tract with the aid of a basket catheter after using chemolysis. PCNL of a renal stone from a transplanted kidney was first described by Hulbert *et al*. in 1985 [44]. Initial publications of case reports were followed by a few series [3, 16, 22, 24, 45]. It is currently the state-of-the-art recommendation for stones larger than 1.5–2 cm. in diameter in transplanted kidneys [16].

The technique differs somewhat from that for a normally located kidney. Obtaining a preoperative CT scan to exclude overlying bowel and aid in planning appropriate percutaneous access is advisable [16]. Ultrasound guidance is recommended to aid in direct calyceal puncture and to avoid potential injury to the bowel [15]. Percutaneous access with fluoroscopy alone is not easy, because of the difficulty in opacifying the collecting system using a retrograde approach [16] (Figure 63.3). In the presence of a complex anatomy around the graft, CT-guided access might be the safest modality [16].

PCNL in normal kidneys is typically performed with an access into the posterior calyx with the patient in the prone position. In contrast, percutaneous access into a transplanted kidney is done with the patient in the supine position and into an anterior calyx. This is due to the anterior location of the transplanted kidney in the true pelvis, along with the change in the axis of the kidney.

Since the diagnosis is usually made by ultrasonography, an interventional radiologist will usually have already placed a nephrostomy tube to relieve the obstruction. Therefore, the patient will present to the urologist with a nephrostomy tube in place. The access is the key to any PCNL; therefore, if the pre-existing nephrostomy tract is not ideal, the urologist should not hesitate to perform another puncture in another location in order to facilitate surgery and prevent kidney damage [16].

Figure 63.5 Percutaneous nephrolithotomy is performed in a supine position in patients with transplanted kidneys. A transplanted kidney is often accessed easily because of its close proximity to the skin. Note that the Amplatz sheath is located mostly outside of the body, due to the short distance between the skin and the graft (courtesy of Ali Ulvi Onder MD).

The transplanted kidney is often accessed easily because of its close proximity to the skin (Figures 63.4 and 63.5) The dense scarring surrounding the kidney may be a nuisance for tract dilation. If balloon dilation

fails initially, Rifaioglu *et al.* recommend another attempt after the balloon is stiffened by placing it in ice slush [16]. In cases when balloon dilation fails, Amplatz dilators or metal Alken sequential dilators may be used. In patients who have undergone previous open or percutaneous surgery, the use of a fascial incising needle, which provides a 4.5-mm diameter fascial opening, may be helpful for balloon dilation [46]. Flexible instruments may be necessary during PCNL owing to the orientation of the transplanted kidney. Rifaioglu *et al*. used a combination of ultrasonic lithotripsy with the rigid nephroscope, and holmium:YAG laser lithotripsy with the flexible endoscope (cystoscope and ureteroscope) [16]. All patients who underwent PCNL had a nephrostomy tube left in place and underwent antegrade pyelography to demonstrate free drainage and stone-free status before tube removal.

A total of 15 patients underwent successful PCNL in a transplanted kidney at the University of California in San Francisco, USA [16]. In all but three patients, access into an anterior upper calyx was achieved, and access was obtained with ultrasound guidance alone or a combination of ultrasound guidance and fluoroscopy. Ten patients had a pre-existing nephrostomy tube, and this was used in all but one patient. Of the 15 patients, eight (53%) were treated with percutaneous flexible nephroscopy/ureteroscopy, and seven had tracts dilated to 30F in order to perform rigid PCNL. All patients were rendered stone free at the end of the procedure without any complications.

He *et al*. described a modified PCNL technique using a miniature endoscope through a small access tract in seven patients [45]. The stone size was between 5 and 45 mm, and all patients were reported to be stone free and free of complications.

Krambeck *et al*. reported on 13 patients with a renal transplant who underwent PCNL [14]. The primary presenting complaint in this cohort was acute renal failure, followed by hematuria, UTI, and pain. Average stone size was 1.36 cm. CT of the pelvis was performed routinely before the procedure. Collecting system access was achieved under ultrasound and fluoroscopic guidance by interventional radiology, which was later dilated to 28F using Amplatz fascial dilators. A single access tract was used in 12, and two tracts were used in one patient. A rigid nephroscope was mainly used; however, flexible instruments were also used to access obscure calyces when necessary. The majority of the patients (77%) were stone free 24 h after the procedure, based on an evaluation with a nephrostogram. Repeat endoscopy was required in three patients to achieve subsequent stone-free status. Postoperative complications developed in three patients, including sepsis, gastrointestinal bleeding, and herpes esophagitis. A single stone recurrence was observed in one patient and treated with SWL at a mean follow-up of 5.3 years. One patient who presented with renal failure prior to stone treatment went on to require a second transplant.

Open surgery

Open surgical approaches should be reserved for patients who fail one of the less invasive procedures. Delayed wound healing and infectious sequelae are potential complications of open surgery in these immunosuppressed patients. In addition, an open surgical approach to the renal pelvis can be technically difficult due to scar tissue, and thus should be reserved for patients who fail PCNL [47].

Conclusions

Transplant urolithiasis requires renal physicians and urologists to maintain vigilance and a high index of suspicion. It is best managed in centers that are well equipped and have expertise to offer the appropriate treatment/intervention. Preferably, there should be access to an on-site lithotripsy machine, flexible ureterorenoscopes with holmium laser, and urologists with significant experience in PCNL. Most patients with calculi of less than 1.5 cm can be rendered stone free with SWL. If this fails, flexible ureterorenoscopy and holmium laser fragmentation may be attempted. For larger stones, PCNL gives the best chance of complete stone clearance.

CHAPTER 64

Stones in Urinary Diversions: Causes and Treatment

Zeph Okeke, Zhamshid Okhunov & Arthur D. Smith
Smith Institute for Urology, North Shore – Long Island Jewish Health System, New Hyde Park, NY, USA

Introduction

The 19th century saw the initial description of the use of the intestine in urinary diversions by John Simon in 1852. In the early 20th century many techniques for this were described; however, success rates were poor and complication rates were high, resulting in their limited application. Improvements in surgical techniques and instrumentation, together with antibiotics and pharmacologic advances, helped to broaden the application of these techniques. Ureterosigmoidostomies are the oldest form of urinary diversion. While it has waned in popularity due to the significant long-term complications, especially related to *de novo* malignancies, it still remains a viable option for a select group of patients. By the 1950s the ileal conduit, as described by Bricker, became the most commonly used form of urinary diversion today. Currently, there is a wide variety of diversion types available to patients requiring urinary diversion.

While most patients with a urinary diversion can expect long-term functionality with minimal morbidity from their diversion, they are not without long-term complications. Most patients with diversions are at increased risk of chronic renal deterioration and urinary tract infection. Common late complications include stomal stenosis, stones in the reservoir, increased stone incidence in the upper tracts, catheterizing difficulties, incontinence in continent reservoirs, and stenosis of the ureterointestinal anastomosis.

Several modifications and advances have been aimed at decreasing the rates of these complications; however, there remains a significant incidence. Often, the most vexing is the increased risk of stone formation in either the reservoir itself or the upper urinary tract. Reducing the incidence and morbidity of these complications with preventive medical management or surgical techniques remains a challenge.

Stone composition

Most stones formed in patients with urinary–intestinal diversions are composed of magnesium and ammonium phosphate. In addition to struvite stones, calcium oxalate, carbonate apatite, calcium phosphate, and ammonium hydrogen urate stones have been reported [1]. Risk factors for urolithiasis include the presence of foreign materials, particularly staples, retained intestinal mucus, chronic colonization of the reservoir with bacteria [2], infection with urease-producing bacteria, as well as increased renal excretion of phosphate, calcium, sulfate, magnesium, and hypocitraturia [3].

Bacteriology

The majority of patients with urinary diversions are colonized with bacteria. Most are colonized with multiple organisms, some of which are uropathogenic. Suriano *et al*. reported on 119 urine cultures taken from the 40 patients with orthotopic ileal neobladders and found a 57% rate of positive cultures: Gram-negative organisms such as *Escherichia coli*, *Proteus mirabilis*,

Smith's Textbook of Endourology, Third Edition. Edited by Arthur D. Smith, Gopal H. Badlani, Glenn M. Preminger, Louis R. Kavoussi.

Citrobacter koseri, and *Kluyvera ascorbata*, as well as the Gram-positive colonizers *Enterococcus faecium, Entrococcus faecalis, Streptococcus mitis*, Group G beta-hemolytic streptococcus, *Enterococcus casseliflavus*, *Staphylococcus aureus*, and *Gemella morbillorum.* Of these, the most prevalent organisms were *E coli, E. feacalis, E. faecium,* and *Proteus mirabilis* [4]. In ileal and colon conduits, the rates ranged from 14% to as high as 96%. It bears mentioning that not all these patients became symptomatic from the colonizing bacteria [5–8]. Typical colonizing bacteria for conduits were predominated by skin flora such as *Streptococcus spp* and *Staphylococcus epidermitis*, though uropathogenic flora were also seen.

Incidence

Stone formation is reported to occur at a rate of 3–11% in patients with the Indiana pouch. This is attributable to the absence of nonabsorbable foreign materials in its construction. This rate increases however with longer follow-up. Terai *et al*. attributed this increased rate to metabolic factors as well as decreased oral fluid intake [1, 3]. The incidence of renal stone formation ranges between 16.7% and 26.5% with the Kock pouch. This is often attributed to exposed staples or nonabsorbable sutures in the reconstructed urinary tract. A rate of 9.8% was reported with the Mainz pouch [9, 10]. The Florida pouch, at a mean follow-up of 6.3 years, had a 15% incidence of stone formation [2]. With a shorter follow-up, the incidence of urinary calculi in hemi-Kock neobladder and Hautmann ileal neobladder was 2.1% and 2.7%, respectively [10, 11]. The introduction where possible of absorbable staples and sutures removes any potential nidus for stone formation [2].

Risk factors for stone formation

Continent reservoirs are at risk for stone formation within the pouch. Risk factors include residual urine, bacterial colonization, and foreign bodies such as metal staples in contact with urine, hypercalciuria, and hypocitraturia. The presenting signs are varied and can include hematuria, infection, sepsis, and obstruction, with reservoir perforation or rupture occurring in very rare cases.

Stones may be characterized as infectious or metabolic but are usually a combination of the two, coupled with a foreign body acting as a nidus. Stones will ultimately recur unless the nidus, usually exposed staples or nonabsorbable sutures, is removed at the time of stone removal [12]. In the study by Terai *et al*. comparing the Indiana and Kock pouches, the authors demonstrated no clear relationship between urinary bacteriology and calculus formation. The infection stones in their study had been formed on foreign bodies and the predominating infectious organisms were urease-producing organisms such as *Proteus spp* and *Providencia spp* [13]. The authors also noted that a small but significant portion of stones were purely metabolic. Long-term increases in urinary calcium, phosphate, and magnesium concentrations, as expected after diversion, were thought to be contributing causes. Increased risk of calcium oxalate formation is not expected secondary to a urinary diversion; therefore, these groups of patients were already predisposed to stone formation unrelated to urinary diversion [3]. However, it is known that diversions utilizing long segments of ileum can induce enteric hyperoxaluria [14].

Struvite stones, reflux, and mucus

Most urinary diversions are constructed without regard to reflux in adult patients. Free reflux of urine from the reservoir or conduit into the upper tracts is a common finding. This reflux of urine allows the colonization of the upper tracts with urea-splitting organisms such as *Proteus spp, Klebsiella spp, Pseudomonas spp, Staphylococcus spp, Providencia spp, Ureaplasma urealyticum, Citrobacter freundii, Enterococcus spp,* and *Streptococcus spp*. These organisms all produce urease which hydrolyzes urea into ammonium and hydroxyl ions, i.e. the breakdown of urea and water into ammonium and bicarbonate ions. The bicarbonate ions raise the pH of the urine.

In the presence of alkaline urine (pH > 7.2), the abundant ammonium ions and phosphate ions result in precipitation of magnesium ammonium phosphate crystals ($MgNH_4$ PO_4•$6H_2O$) and carbonate apatite (Ca_{10} (PO_4) 6•CO_3) crystals, so-called struvite stones. These stones are often also composed of a core or interspersed layers of matrix from mucoproteins that refluxed from the conduit.

Hyperchloremic metabolic acidosis is a common finding in patients with urinary diversions, particularly when ileal and colonic segments are used in the construction of the urinary reservoir. The prolonged contact of urine with the bowel segment leads to exchange of bicarbonate and chloride ions, such that a serum acidosis results from an excess of hydrogen ions in the serum. The acidemic state results in impaired reabsorption of calcium from the proximal tubules and decreased renal production of citrate. Additionally, increased reabsorption of citrate from the urine by the exposed intestinal segments may be present. The resulting hypercalciuria, hypocitraturia, alkaline urine, and urinary abundance of ammonium and phosphate ions all favor stone formation.

Oxalate stones

Loss of ileum results in varying degrees of intestinal malabsorption. This condition is commonly seen in

patients after resection of ileum for colon cancer or inflammatory bowel diseases such as Crohn's ileitis. In patients with urinary diversions, the length of ileum resected is directly correlated with the postoperative risk of stone formation, with patients having longer segments resected being more prone to stone formation. The fatty acids and bile salts that are normally absorbed in the ileum pass into the colon where they undergo saponification by binding with calcium. With less calcium available to bind oxalate in the intestines, there is an abundance of free ionized oxalate, which is readily absorbed by the intestines and excreted by the kidneys. This leads to hyperoxaluria which in turn leads to increased kidney stone formation.

Urate stones

If chronic diarrheal states result after using a bowel segment for urinary diversion, hyperuricemia and hyperuricosuria can develop. Often, however, the cause of the hyperuricosuric state is unknown in the absence of overindulgence of purine-rich foods.

Surgical management

Conservative management with observation for spontaneous passage, extracorporeal shock-wave lithotripsy (ESWL), antegrade and retrograde ureteroscopic manipulation, percutaneous nephrolithotomy (PCNL), and percutaneous or transstomal reservoir or conduit lithotripsy, are all management options available for treating patients with urinary diversions. The management approach chosen depends on the location, stone size, patient's reconstructed anatomy, and underlying cause of the stone. Historically, open surgical extraction was the only option for managing stones in diversions. However, newer minimally invasive techniques coupled with advances in endosurgical tools have made open surgery a very rare necessity. With these new advances came decreased morbidity, length of hospitalization, and faster recovery (see Video 64.1).

In cases where there is no ureteral reflux from the reservoir into the upper tracts, percutaneous access can be challenging. In this scenario, ultrasound guidance is necessary to locate the kidney for initial access. Under ultrasound guidance access can be obtained into the collecting system, allowing an antegrade nephrostogram to be performed, and then a more optimal access location can be obtained in the usual manner using fluoroscopy. Alternatively, anatomic landmarks can be used to gain initial blind access into the renal pelvis. Again, once access is obtained into the collecting system, a nephrostogram can be performed, and the optimal calyx for percutaneous nephrolithotomy can then be chosen under fluoroscopic guidance.

When ureteral stones are located along the approach to the conduit or reservoir, especially the segment of the left ureter that is tunneled under the root of the mesentery (see Figure 64.3), maneuvering and maintaining the flexible ureteroscope into an optimal and favorable position can be especially challenging. In a similar fashion, stone basketing is also often challenging in this location. The more flexible stone baskets, such as nitinol baskets, are often the best choice since they do not interfere as much with the deflectability of the ureteroscope as other stiffer baskets. At other times, however, a stiffer basket may be necessary to allow for greater pulling force while entrapping the stone; this can often be useful for stones that are embedded within the wall of the ureter.

Once stone clearance is completed, it is important to inspect and evaluate the ureteroileal anastomosis, and to perform a biopsy as needed to check for recurrence of tumor. Often, however, stricture and stenosis are found, and these need to be addressed. In the absence of tumor recurrence, a combination of dilation and incision can often yield good results and maintain patency of the anastomosis.

Stones in the kidney and ureter

For the most part, upper tract calculi in patients with urinary diversions can be managed similarly to patients without diversions, with certain special considerations. The major consideration involves the optimal approach to the ureter. Initial management for most calculi in patients with urinary diversions includes observation for spontaneous passage, ESWL, antegrade or retrograde ureteroscopic lithotripsy, PCNL, and trans-stomal or percutaneous pouch lithotripsy. For diversions with narrow-lumen stoma, such as the Mitrofanoff valve or Indiana pouch, manipulation through a transstomal approach may result in a stricture and difficulty with catheterizations, or in loss of the continence mechanism.

Incontinent diversions (Figures 64.1–64.3)

Loop diversions are the most commonly performed incontinent diversions. The surgical technique for their construction has not changed since their introduction. Ileal segments are most commonly used, although other bowel segments such as transverse and sigmoid colon and, less commonly, jejunum have been used. Metabolic consequences are similar for these segments, with the exception of jejunal segments. Stone formation within the loops are mostly due to passage from the upper tracts, presence of a foreign body such as exposed staples and sutures, residual urine, or stomal stenosis [15, 16].

To adequately address stones passing from the upper tract, detailed knowledge of each patient's unique

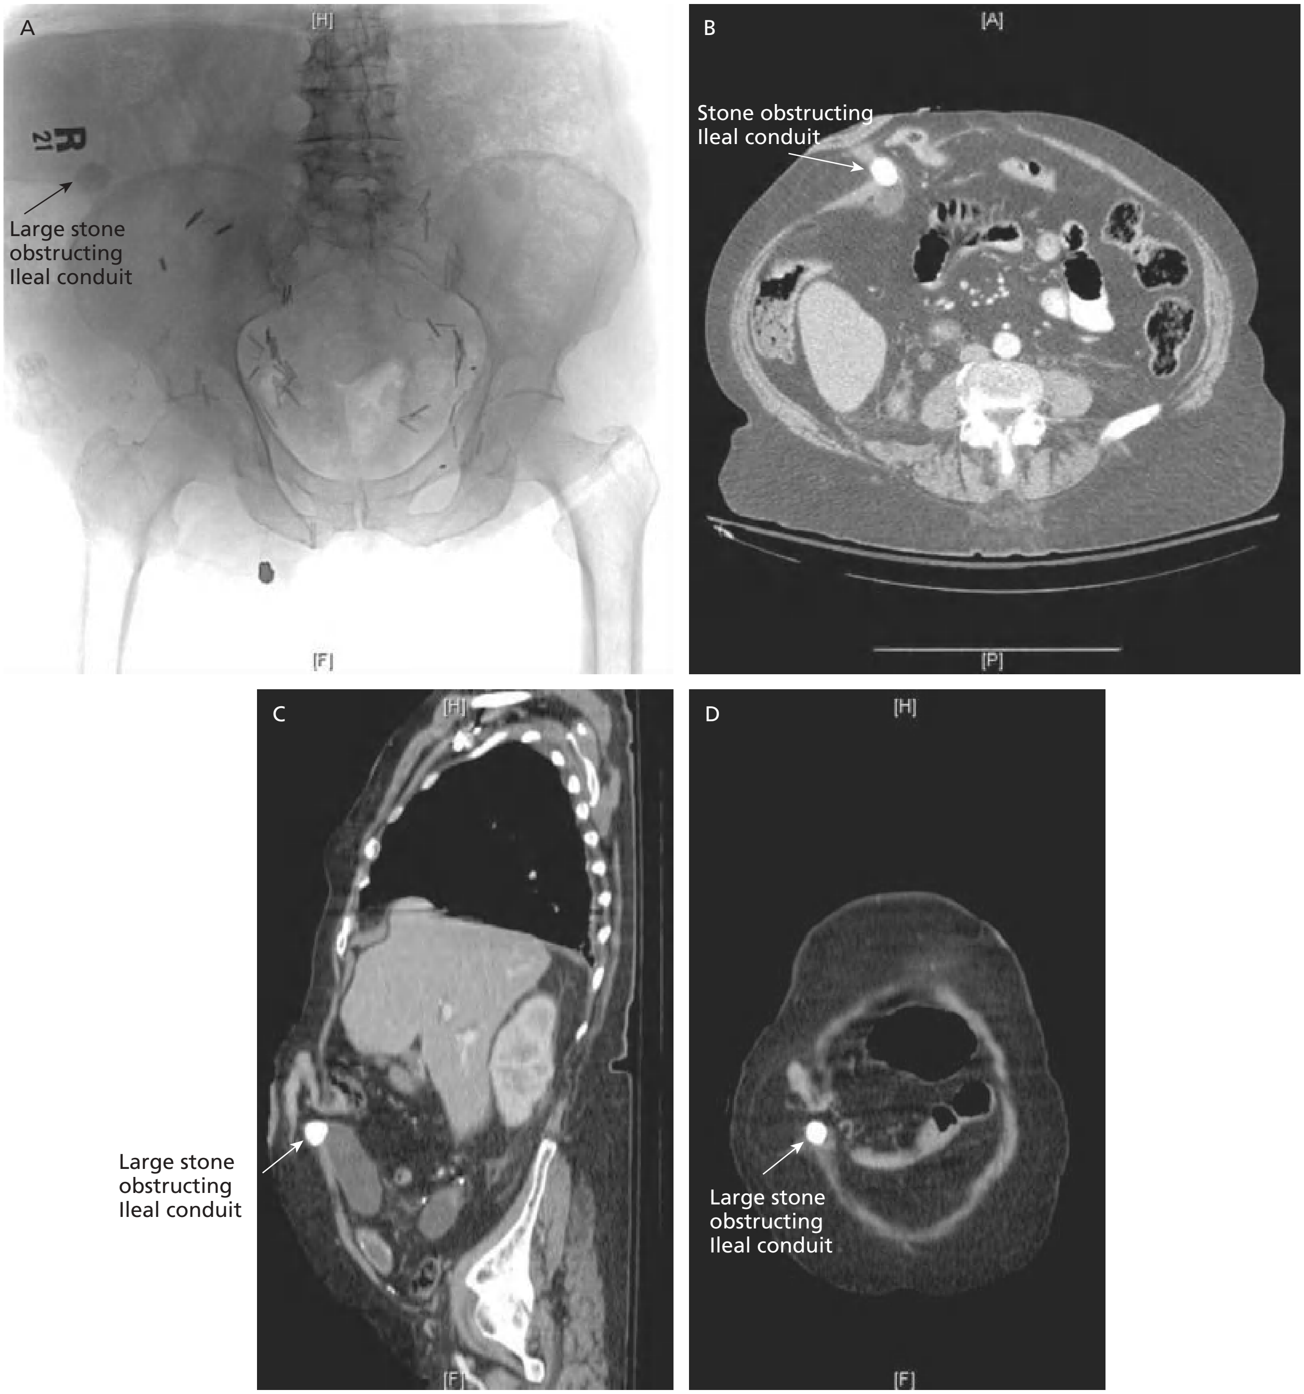

Figure 64.1 Large stone completely obstructing ileal conduit. (A) Anteroposterior view; (B) axial view; (C) sagittal view; (D) coronal view.

reconstructed anatomy is crucial. Contrast-enhanced CT with delayed imaging is useful. ESWL is a good initial treatment for small upper tract stones. Also, a renal scan may be useful in assessing for obstruction at the ureterointestinal anastomosis. If the anastomosis is patent, a retrograde approach can be used to address upper tract stones. Placement of a ureteral access sheath and superstiff guidewires can aid in retrograde passage of instruments, especially in very redundant loops. Percutaneous access may be necessary for antegrade placement of guidewires, followed by retrograde techniques. For stones within the loop or close to the ureterointestinal anastomosis, the foreign body nidus needs to be removed as well after stone removal. Stomal stenosis, if not addressed, can lead to upper tract deterioration, increased residual urine, and possible perforation of the

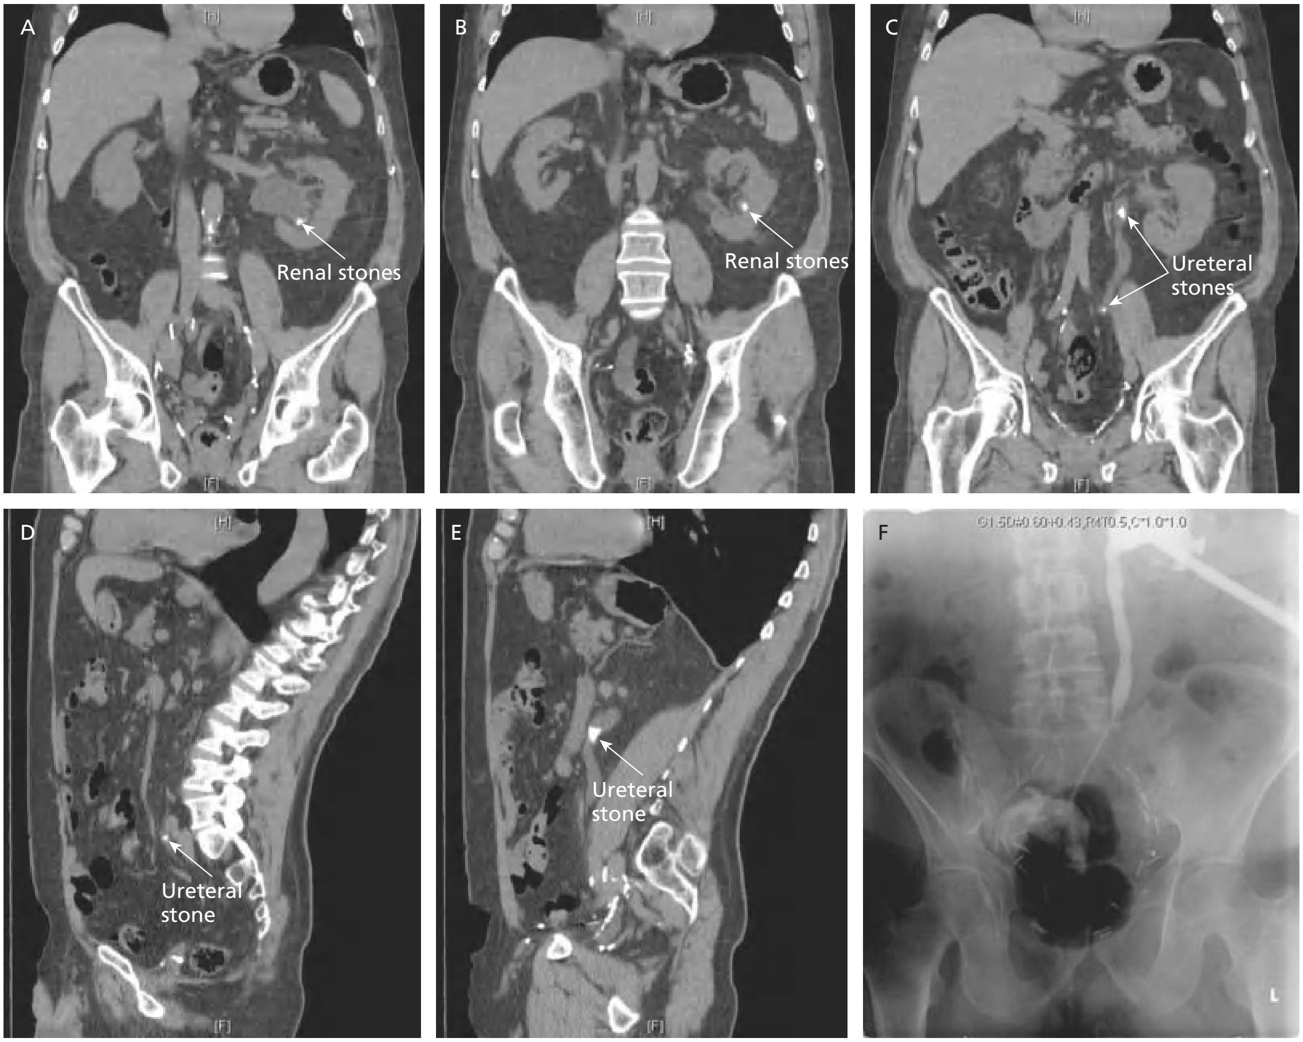

Figure 64.2 (A, B) Renal and (C–E) ureteral stones in a patient with ileal conduit. (F) Postoperative nephrostogram.

conduit. A loopogram can aid in the diagnosis of stomal stenosis and, if present, will need revision in addition to removal of the stone().

Continent diversions (Figures 64.4–64.7)

Much like loop diversions, low pressure–high volume pouch continent diversions can be constructed using the stomach, ileum, or colon. Most often, the right colon and ileum are used. They can be placed in an orthotopic location and anastomosed to the native urethra, or cutaneous catheterizable stomas can be constructed. The continence mechanisms vary from appendix to tapered ileal segment for cutaneous diversions, and native striated urethral sphincter for orthotopic diversions [17, 18].

For continent diversions, risk factors for stone formation are directly related to residual urine, mucus accumulation due to lack of irrigation, acidic urine, and bacterial colonization [1, 19, 20]. Maintenance of the continence mechanism is of paramount importance as this can be very tenuous. Due to the risk of incontinence and strictures or stenosis, stomal access is discouraged for continent diversions, except as a means to fill the pouch. If the stone burden is minimal, then stomal access for continent diversions or urethral access for orthotopic pouches, can be used with rigid or flexible instrumentation. Fragmentation can be performed with any of the available techniques: holmium laser, pneumatic, mechanical or electrohydraulic lithotripters. For larger stone burdens or when there is concern about damage to the continence mechanism, a percutaneous approach should be used.

For pouch access, it is imperative to review preoperative CT scans to determine the location of adjacent bowel and other vascular structures. Ultrasound guidance may also be a useful aid intraoperatively. One technique is placement of a flexible endoscope through the stoma or urethra and deflecting anteriorly to transilluminate the

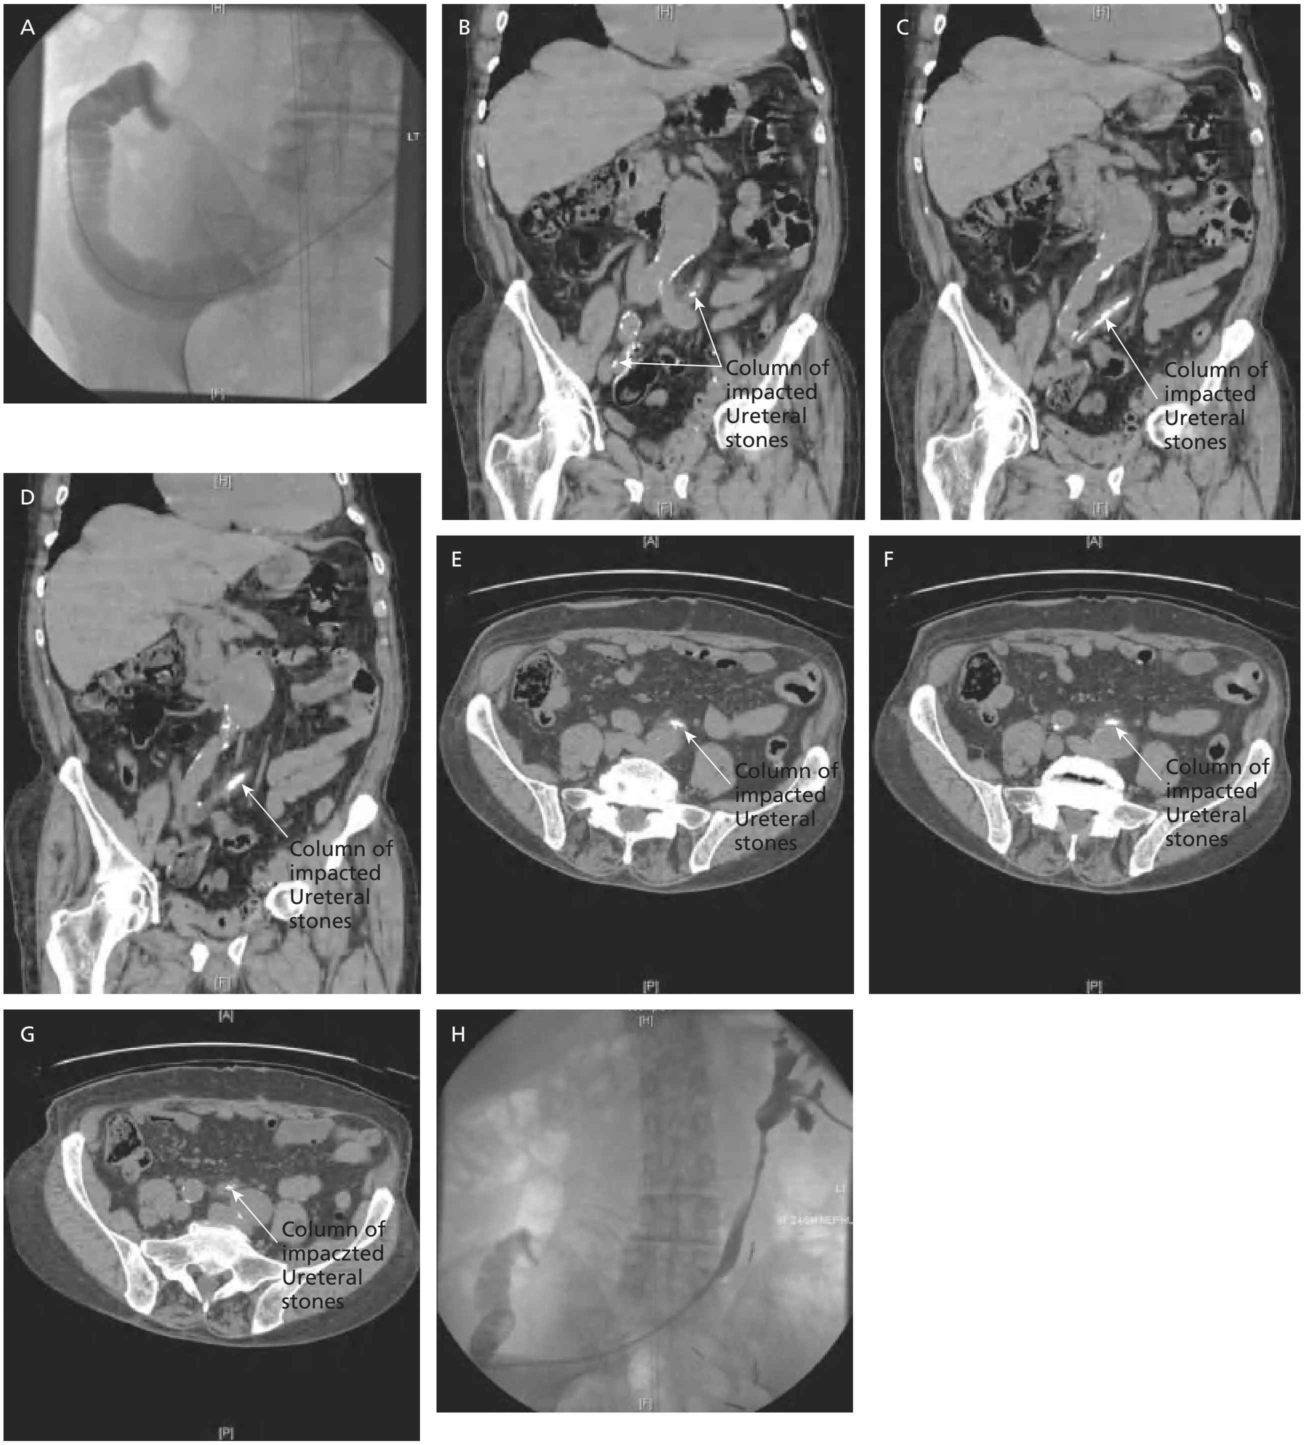

Figure 64.3 (A) Redundant ileal loop in a patient with a (B–G) column of impacted ureteral stones. (H)Postoperative nephrostogram.

proposed site, followed by percutaneous puncture onto the light. In this manner, the entire access and dilation can be performed under direct visualization. Once dilation is completed, Amplatz-type sheaths or laparoscopic trocars can be used. For the laparoscopic approach, separate camera and working ports can be placed as needed. Fluoroscopic guidance is indispensable since stones can be hidden behind folds within the pouch. With the sheath in place, a rigid nephroscope with its sizeable working port can be used with any of the intracorporeal lithotripters. Fragment extraction can become problematic, but this can be easily overcome by placing a

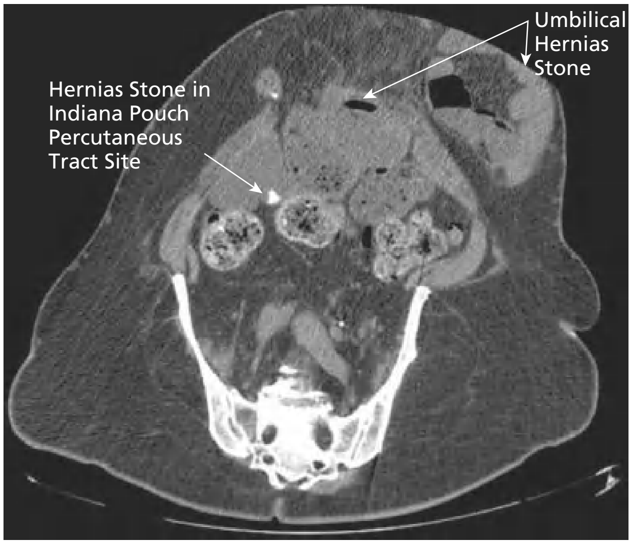

Figure 64.4 Stone in an Indiana pouch. Arrow identifies the ideal percutaneous tract.

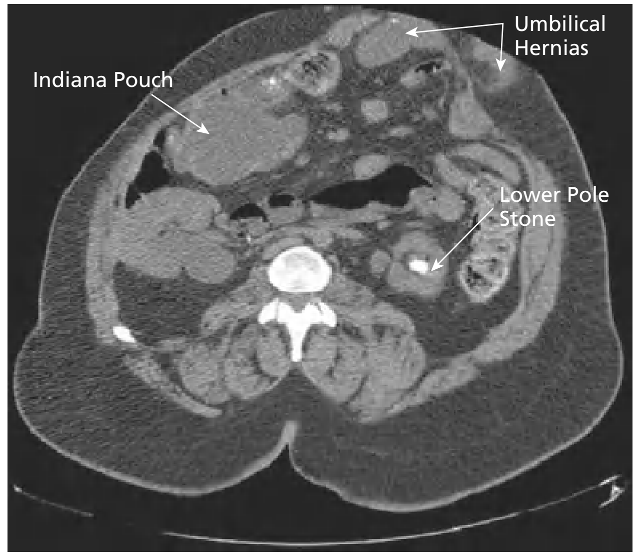

Figure 64.5 Lower pole renal stone in a patient with an Indiana pouch.

Figure 64.6 Stone in an Indiana pouch.

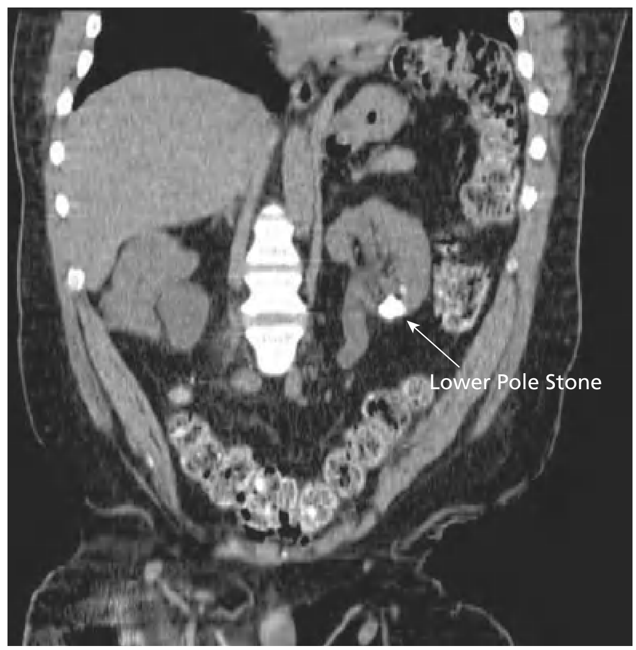

Figure 64.7 Lower pole renal stone in a patient with an Indiana pouch.

laparoscopic Endo-catch entrapment bag to hold the stones. Lithotripsy can then proceed inside the bag. An alternative approach is to widen the skin incision and extract the bag with the stones intact [21–27]. Laparoscopic ureterolithotomy is also an option; however, this requires advanced laparoscopic skills. Open cystolithotomy is also an option, but is very seldomly used given the availability of minimally invasive percutaneous techniques [28–32] (Figures 64.1, 64.4–64.7).

Cohen *et al.* recommend ultrasonic over electrohydraulic lithotripsy, since the stones can be fragmented and evacuated with suctioning with fewer passes of the instrument across the efferent limb, thereby decreasing risk of injury. Additionally, the ultrasonic waves do not injure the intestinal mucosa, in contrast to the electrohydraulic lithotripter which can cause significant mucosal trauma [12]. Most authors agree that ESWL with or without trans-stomal endoscopic extraction can be effective for small stone burdens. These approaches are limited by small stoma size and the continence mechanism, which restrict the use of larger size instruments capable of treating larger stones.

In the hands of a skilled endourologist, minimally invasive approaches may be used to treat large stones up to 4–5 cm in diameter [21] and even multiple pouch calculi in patients with continent diversions, without disrupting the continence mechanism [12]. Other authors have demonstrated that in the right hands, trans-stomal endoscopic removal of stones results in minimal complications, while anesthetic requirements and length of hospitalization are reduced [33]. However, all continence mechanisms are not alike and therefore, it is cautioned that the trans-stomal approach be reserved for diversions with intussuscepted nipple valves of adequate caliber to easily accommodate larger instruments for more efficient stone removal [34].

Percutaneous techniques can be challenging because small fragments can easily be obscured in the mucosal folds of the bowel. These fragments will then act as a nidus for regrowth of new calculi. Even with copious irrigation, the fragments may remain. A second-look endoscopy of the reservoir is of benefit since this can further increase the stone-free rates [35–37].

Drainage

Once stone extraction is completed, the choice of drainage is important. The options include ureteral stents, pigtail nephrostomy tubes, re-entry nephrostomy tubes, nephroureteral tubes, among others. If a completely indwelling drainage system is desired, ureteral stents are the optimal choice. It is important to choose an extra-long ureteral stent to facilitate its removal via a retrograde approach from the reservoir. Often, a string can be left dangling from the stent and out through the stoma to avoid instrumenting the patient when removing the stent. For renal or ureteral stone removal performed through an antegrade approach, a pigtail nephrostomy tube, a nephroureteral tube, or even a re-entry nephrostomy tube can be used, based on the surgeon's preference. If percutaneous access was gained into the reservoir, a separate drain can be placed through the puncture site into the reservoir and removed once the urine is sufficiently clear of blood clots and debris. In cases where strictures are treated, a period of stenting of at least 4–6 weeks is customary before removal of the stent or nephroureteral tube. It is important to reassess the anastomosis after removal of the stent to assure patency. Some patients may ultimately require open reconstruction to revise the anastomosis if the stricture persists.

Prevention and medical management

Lifelong prophylaxis is critical in this patient population because of the high recurrence rate, which Cohen *et al*. estimated to be as high as 63% over 5 years [38]. Adequate oral fluid intake, as in all patients prone to renal calculi, is essential to prevention [39]. Terai *et al*. in their examination of Indiana pouch calculi found no significant difference in most urinary risk factors between patients with and without stones, except for 24-h urine volume, which was significantly lower in stone formers (mean 2.0 L vs 1.6 L, $P < .05$) [1]. These at-risk patients should ideally have a daily urinary output of at least 2 L to significantly impact the risk of stones recurring [39].

Terai *et al*. reviewed overall stone formation rates in diversions performed in the USA and Japan, and found the the Indiana pouch had significantly higher rates of stone formation in Japan. Considering that the overall predisposition for stone formation is lower in Japan than in the USA (5.4% vs 12% lifetime risk of urolithiasis, respectively [40]), the authors identified that the only difference in protocol was the use of frequent pouch irrigations in the USA. Hensle *et al*. demonstrated a significantly lower rate of stone formation for patients placed on a standard prophylactic irrigation protocol [41]. Dumanski *et al*. has postulated that small crystals and intestinal mucus that are not drained with catheterization alone may act as a template for bacterial biofilms and consequently as a nidus for the growth of infection stones [42].

Other prophylactic measures include a regular voiding and catheterization schedule in order to decrease residual urine volume within the reservoir. Complete evacuation is essential since residual urine is considered a more significant risk factor than bacteriuria for calculus formation [9, 43].

As with any patient with recurrent urinary calculi, predisposing metabolic abnormalities also need to be addressed. As many as a third of these patients have low urinary citrate levels (100 mg/day) and are more prone to stone formation [3]. They may be chronically acidotic, which inhibits the renal production of citrate, resulting in hypocitraturia [44]. Decreased urinary citrate levels may also be secondary to decreased renal production of citrate, increased intestinal reabsorption of citrate by the diversion, or a combination of the two [45]. For these patients, oral citrate supplementation is indicated.

Urinary reservoirs are frequently colonized by bacteria. Urea-splitting organisms are often found and they are responsible for the formation of magnesium ammonium phosphate stones. If a struvite stone is found, antibiotic therapy is indicated. If stones recur, then prophylactic antibiotics should be considered. Also, the importance of increased fluid intake should not be ignored [9]. Prophylaxis for struvite stones can also include acetohydroxamic acid, which is an irreversible urease inhibitor [46]. Dissolution therapy for struvite calculi may be effective in eliminating stone fragments. Hemiacidrin or Suby's G solution dissolves struvite and

calcium phosphate stones by acidifying the urine and forming calcium–citrate ion complexes [47]. Aluminum hydroxide is another option. It acts by binding phosphate in the gut, thereby decreasing gastrointestinal absorption of phosphate.

Conclusions

Management of urolithiasis continues to be a significant challenge in patients with urinary diversions. Prevention and prophylaxis remain the most important management strategies. Prophylaxis with increased fluid intake, regular voiding and catheterization schedules, frequent pouch irrigation, antibiotic prophylaxis, and when indicated, other adjuncts such as citrate supplementation or use of urease inhibitors, are all of tremendous importance as management strategies. Additionally, elimination of any nonabsorbable elements during construction of the diversion will serve to lower the incidence of stone formation. Minimally invasive and endourologic techniques have broadened the available choice in the surgical management of these patients, decreasing the morbidity and shortening the convalescence associated with treatment of these stones.

CHAPTER 65

Management of Pediatric Stone Disease: Endourologic Techniques*

Marc C. Smaldone, Daniel P. Casella & Michael C. Ost

Division of Pediatric Urology, Children's Hospital of Pittsburgh, Department of Urology, University of Pittsburgh School of Medicine, Pittsburgh, PA, USA

Introduction

The surgical management of urolithiasis in children is dramatically evolving. Over the past two decades, the advent of shock-wave lithotripsy (SWL) has revolutionized pediatric stone management and SWL is currently the procedure of choice in treating most upper tract calculi in industrialized nations. However, with miniaturization of equipment and refinement of technique, endoscopic access to the entire pediatric urinary tract is now possible, and in westernized countries open stone surgery has become obsolete. In a growing number of centers, ureteroscopy (URS) is being performed in cases that previously would have been treated with SWL or percutaneous nephrolithotomy (PCNL), with demonstrable efficacy and complication rates in retrospective series. This chapter provides a directed review of the literature, focusing on recent advances in the surgical management of pediatric stone disease.

Incidence of urolithiasis in children

The incidence and characteristics of nephrolithiasis in children reflect a wide geographic variation, but stones occur in children of all ages without clear gender predominance [1]. Although uncommon in the western hemisphere, pediatric stone disease is considered endemic in developing nations, including India, Turkey, Pakistan, and the Far East. In these areas, ammonium acid urate and uric acid stones predominate, strongly implicating dietary factors [2]. Despite this discrepancy between hemispheres, nephrolithiasis in children is increasing in occurrence globally [3], likely reflecting westernized lifestyle and dietary changes, including higher salt and carbohydrate intake with processed foods and decreased water consumption [4].

It is established that children with anatomic abnormalities, urinary tract infections, and metabolic disturbances are considered to be at high risk for stone development [5]. In developing nations, recent reports suggest that a metabolic risk factor can be found on urine studies in 84–87% of children, most commonly hypercalciuria or hypocitrauria [6, 7]. However, evidence is accumulating that stones in a majority of westernized children are calcium based without any evidence of metabolic abnormality on 24-h urine collection [8]. In a retrospective study of 1440 Pakistani children, Rivzi *et al*. reported that while diet, dehydration, and poor nutrition remain the major causative factors of pediatric nephrolithiasis, there is an emerging predominance over the past decade of upper tract calculi, which is more consistent with adult populations [2]. Recent data support this trend: in a modern series of 150 children managed over an 8-year period, Kalorin *et al*.

Smith's Textbook of Endourology, Third Edition. Edited by Arthur D. Smith, Gopal H. Badlani, Glenn M. Preminger, Louis R. Kavoussi.

reported that 57% of stones detected in children younger than 10 years of age were located in the upper tract [9].

Diagnosis

Radiologic evaluation and surveillance

Radiographic assessment of the child with calculus disease must be accurate, economic, and safe**.** The goals include determination of stone location, size, density, and urinary tract anatomy. Indications for assessment include acutely symptomatic children with a suspected calculus, or children with known calculus disease requiring follow-up evaluation to either determine stone burden or recurrence. Radiographic evaluation is also important in children with abnormal urinary tract anatomy that may predispose to calculus formation requiring eventual surgical management. Renal calculi in neonates and younger children are often diagnosed with ultrasound. While anatomic location and the associated presence of hydroureteronephrosis can be accurately assessed in a majority of children, up to 40% of calculi may be missed using ultrasound [10]. Despite the increased sensitivity of computed tomography (CT) compared to ultrasound [11], concerns regarding radiation exposure limits its use in young children. Although speculative, risk as high as one fatal cancer for every 1000 CT scans performed in young children have been reported [12]. Recently, investigators have begun to reassess diagnostic thresholds in an effort to reduce radiation exposure without sacrificing diagnostic efficacy, particularly in children with complex stone histories requiring serial imaging studies [13]. Radiation exposure can also be reduced effectively by reducing the number of CT examinations performed for poor clinical indications, scanning only the anatomic region of interest, and by not performing both unenhanced and contrast-enhanced scanning unless absolutely necessary [14].

In our practice, asymptomatic calculi incidentally diagnosed with ultrasound are followed with serial ultrasound or plain abdominal films to minimize radiation exposure. Noncontrast helical CT is our diagnostic test of choice in older children presenting acutely with flank pain, but is reserved for younger children in whom plain films or ultrasound are nondiagnostic. CT can also be useful in demonstrating secondary signs of acute obstruction, such as hydroureteronephrosis, renal enlargement, and perinephric or periureteric stranding; however, the latter findings may be less obvious or absent in pediatric patients due to their comparatively less retroperitoneal fat [15–17]. Postoperative or surveillance imaging is individualized and based on age, anatomy, stone burden, and any underlying metabolic abnormality with the goals of maintaining diagnostic accuracy as well as minimizing radiation exposure.

Fluoroscopy has an important role in the realtime detection and management of urolithiasis in children, and the same important safety concerns exist with respect to radiation exposure as with CT. C-arm fluoroscopy is utilized during the surgical setting to assist in antegrade and retrograde access of the upper and lower urinary tract, and manipulation of endoscopic instruments *in vivo* often requires realtime fluoroscopic monitoring. Fluoroscopy is also used during SWL to assist in stone localization and to monitor the effectiveness of treatment. Pediatric endourologists must have a working understanding of the principles of fluoroscopy and be aware of the intraprocedure fluoroscopy time and energy settings to limit radiation exposure to both the pediatric patient and operative staff.

Metabolic evaluation

Following definitive therapy, children are ideally followed in a multidisciplinary stone clinic, including urologic, renal, nutrition, and endocrine evaluation if necessary. Routine evaluation includes urine culture, 24-h urine collection, and office-based ultrasound or abdominal films to detect recurrence. While there is abundant reference material in the adult literature, data regarding standard 24-h urine reference values for stone risk factors in children are just beginning to emerge [18]. Regrettably, there are significant differences between the normal ranges of urine chemistries in children and adults [19, 20], and standardizing 24-h urine parameters for nonstone formers is currently the subject of prospective evaluation at our institution.

In the preliminary evaluation of pediatric stone disease it is common to obtain 24-h urine values for creatinine, sodium, calcium, oxalate, uric acid, and citrate. The very cumbersome nature of a 24-h urine collection often limits its accuracy in the pediatric population. In light of this, random urine spot sample ratios have been used. Urine calcium-to-urine creatinine ratios (Uca:Ucr), for example, have been used with sensitivities and specificities up to 90% and 84%, respectively, in the evaluation of hypercalcuria, a known risk factor for urolithiasis [21]. However, a single test limited to one urinary metabolite cannot be solely relied upon to monitor responses to various medical treatments. Furthermore, it is unreasonable to solely rely on urinary calcium excretion values as an indication of overall metabolic disturbances. It has been suggested that measurement of urinary supersaturation products (calcium oxalate, urate) may help to improve the identification of those children at risk for stone formation. DeFoor *et al.* demonstrated that supersaturation levels of calcium oxalate as well as calcium-to-creatinine ratios

were significantly higher in pediatric stone formers compared with control subjects [22]. However, this observed difference may reflect differences found in urine volumes. Lande *et al*. recently observed that low urine volumes in children often negate the benefit of pursuing urine supersaturation products in a stone metabolic work-up [23].

Medical management

Stone disease in the pediatric population has contributing genetic, anatomic, metabolic, and dietary causes. There are numerous genetic causes of hypercaliuric nephrolithiasis alone that contribute to pediatric calculi formation [24]. Taking this into account, proper medical management is essential following spontaneous passage or definitive surgical therapy. Although a detailed assessment of the medical management of pediatric stone disease is beyond the scope of this chapter, a focus on prevention through diet and medication monitoring is crucial to long-term management, and often involves consultation with a pediatric nephrologist.

Conservative management

Conservative management of pediatric nephrolithiasis closely mirrors that of adults. Even in very young children, renal calculi of less than 3 mm are likely to spontaneously pass, and stones of 4 mm or larger in the distal ureter are likely to require endourologic treatment [25]. In our practice, if a child's pain is controlled with oral analgesia, clear liquids are tolerated, and there is no evidence of urinary tract infection, parents are offered a closely monitored trial of spontaneous passage for 4–6 weeks prior to definitive therapy. Based on efficacy demonstrated in the adult population [26], tamsulosin may be offered on an individualized basis as adjunctive therapy to facilitate ureteral expulsion, although there is limited current evidence supporting its effectiveness in children [27]. A ureteral stent is placed acutely in children with evidence of an infected genitourinary system, refractory colic, or uncontrolled nausea and vomiting. Under these circumstances definitive therapy is delayed for 7–14 days following stenting to allow for system decompression, ureteral orifice dilation, and resolution of edema before endourologic management is undertaken [4].

Pediatric considerations

Special considerations in the endourologic management of stone disease in children include preservation of renal development and function, prevention of radiation exposure, and minimizing need for retreatment. Despite advances in endourologic equipment and technique, controversy remains regarding the contribution of SWL to future development of diabetes or hypertension, and whether ureteral orifice dilation during URS leads to ureteral stricture formation or development of vesicoureteral reflux (VUR). International consensus is lacking as to the most effective surgical management of pediatric stone disease due to lack of prospective randomized trials comparing treatment modalities and disparity in the access to emerging technologies. Regardless of treatment modality, the presence of residual stone fragments is associated with adverse clinical outcome [28], and every attempt should be made to achieve a stone-free status. Surgeon experience is paramount to facilitate complete stone clearance and minimize retreatment rates [4]. The decision regarding the most efficacious primary treatment modality must be individualized per child based on age, anatomy, location, and composition of stone burden.

Antibiotic use

Use of perioperative antibiotics in the management of pediatric urolithiasis closely mirrors that in adult patients. Per the 2008 American Urological Association best practice statement on antibiotic prophylaxis, 24 h or less of perioperative antibiotics are indicated in all patients undergoing upper tract instrumentation [29]. Appropriate agents include fluoroquinolones, trimethoprim–sulfamethazole, first- and second-generation cephalosporins, and ampicillin in combination with an aminoglycoside. A urine culture is mandatory before all upper tract procedures to determine if the urine is sterile, and culture results are used to guide preoperative antibiotic therapy, particularly for percutaneous procedures, patients with high-grade obstruction, or patients with an indwelling stent [5]. In our practice, children with a negative urine culture undergoing uncomplicated SWL and URS procedures receive perioperative cefazolin, and all children undergoing a percutaneous procedure or who have a preexisting ureteral stent/nephrostomy tube receive a fluoroquinolone or ampicillin/gentamicin. Use of postoperative antibiotics is controversial and is determined on a per child basis and individual surgeon preference. Recent data demonstrating an increased risk of developing resistant bacterial strains with prolonged use of antibiotic prophylactic therapy [30] have led to many pediatric urologists reconsidering the need for and duration of postprocedure prophylaxis.

Shock-wave lithotripsy

The emergence of SWL revolutionized the minimally invasive treatment of urolithiasis during the early 1980s. Initially reported in children in 1986 [31], large series

have reported complication, safety, and stone-free rates comparable to adults [32–39] (Table 65.1). When used as a primary treatment option for upper tract calculi, SWL efficacy ranges from 68% to 84% [32, 35, 40] and has become the preferred treatment modality for uncomplicated renal and proximal calculi of 15 mm or smaller. In a contemporary series of 216 children (mean age of 6.6 years) with a mean stone size of 14.9 mm undergoing SWL with the Dornier HM3 lithotripter, Landau *et al*. reported a 3-month stone-free rate of 80%, demonstrating that efficacious stone-free rates can be achieved in appropriate candidates [41]. Complication rates are minimal, and range in severity from hematuria and ecchymosis to obstruction with sepsis [42]. Although well tolerated in children, current stone-free rates with SWL are difficult to interpret from the existing body of data due to discrepancies between studies with regard to type of lithotripter, number of shocks administered, and retreatment rates [43]. Recent data suggest that stone-free rates in children with a history of a urologic condition or urinary tract reconstruction are quite low (12.5%), and these children may be better served with URS or PCNL [44]. Despite encouraging results, SWL has not been approved by the Food and Drug Administration for use in children, although it is a widely accepted treatment modality.

Technique in children

General anesthesia is administered in a majority of preadolescent children to avoid patient and stone motion and the need for repositioning. With modern lithotripters, intravenous sedation has been successfully employed in select older children [45], but bowel

preparation is now rarely utilized to avoid postoperative dehydration and electrolyte imbalances. The number of shocks delivered and the kilovoltage used vary per lithotripter, but the current consensus recommends that low power settings (17–22 kV) be used to prevent stone migration during the procedure, with an approximate goal of 3000 shock waves per session (<2000 in very young children) [42]. A recent report assessed and compared the number and intensity of shock waves required for stone fragmentation in 44 children (mean age 5.9 years) and 562 adults (mean age 40.9 years). With an equivalent number of sessions between groups (1.1 in each), the mean number of shock waves (950 vs 1262, $P < .001$) and the kilovoltage required (11.8 kV vs 12.4 kV, $P < .001$) were significantly reduced in the pediatric cohort [46]. Although controversial and dependent on stone burden and anatomy, we do not routinely stent children prior to SWL. Ureteral catheters are occasionally employed to aid in the localization of radiolucent calculi, and relative indications for preoperative stenting include solitary renal units, staghorn calculi, obstruction, or anatomic variants [43].

Stone size, location, composition, and patient age

While early series focused primarily on the feasibility, safety, and efficacy of SWL in children, recent efforts have centered on identifying demographic, anatomic, and stone-related prognostic factors for treatment success. SWL is currently considered the primary treatment for upper tract calculi of 15 mm or smaller in children [42], but evidence supporting this stone size cut-off is lacking [43]. Ather *et al*. analyzed the correlation between stone size and clearance in 105 children younger than 14 years of age. They reported an overall stone-free rate of 95% after a mean of 1.7 treatments, with 5% of patients requiring additional procedures as adjuncts to SWL. With a maximum of 30 mm, mean stone size in the treatment success group was 14 mm compared to 16 mm in the treatment failure group [36]. In contrast, using two second-generation lithotripters in 148 children and adolescents, Elsobsky *et al*. reported stone-free rates of 91% versus 75% for mean stone diameter less than and greater than 10 mm, respectively [33]. Investigating stone-free outcomes with the Dornier DoLi S device in 24 children with large stone burdens (mean stone size 31 mm), Shouman *et al*. reported stone-free and complication rates of 83% and 25%, respectively, utilizing 53 sessions and a mean number of 3489 shock waves per session [47]. While these series demonstrate that it is possible to treat very large stone burdens with SWL, the necessity of greater number of shock treatments, more frequent retreatment sessions, and increased risk of postoperative obstruction are still concerning. Further study delineating a clear size cut-off for uncomplicated upper tract stone burden is required to effectively counsel parents regarding the most effective first-line therapy for renal calculi between 1 and 1.5 cm [43].

Renal anatomy and stone location have been subjects of recent interest. The subject of frequent debate in the adult population, the most effective management of lower pole calculi in children has yet to be determined. Stone-free rates from initial small retrospective SWL series range from 56% to 61% [48, 49] with retreatment rates as high as 40% [49]. SWL failure and retreatment rates were associated with increased mean stone burden [49], increased infundibular length [48], and infundibulopelvic angle greater than 45° [48]. Staghorn calculi are uncommon in children and represent a management challenge. Although monotherapy success rates are low in adults, acceptable stone-free rates in children have been achieved with SWL. In 23 children stratified by age with a mean stone burden of 1.6 cm, Lottmann *et al*. reported an overall stone-free rate of 82.6% with only one case of symptomatic obstruction. A ureteral stent was placed in 22% of children, and these authors reported an 88% stone-free rate in children younger than 2 years of age compared to 71% in children aged 6–11 years [50]. In 42 children with a mean stone burden of 3.2 cm stratified by ureteral stent placement, Al-Busaidy *et al*. reported an overall stone-free rate of 79%. While stent placement did not affect stone-free rates, they found that stent placement significantly reduced the major complication rate [51]. The superior success rates with SWL monotherapy in children compared to adults have been attributed to softer stone composition, smaller relative stone volume, increased ureteral compliance to accommodate stone fragments, and smaller body volume to facilitate shock transmission [43]. SWL safety and efficacy have been demonstrated even in very young children. McLorie *et al*. treated 34 children younger than 3.5 years old (mean age 23 months) and reported an 86% overall stone-free rate (66% after one treatment) without major complications [52]. Treatment of proximal ureteral stones has achieved similar success rates to renal stones in most pediatric series, although ureteral stenting is more commonly employed to aid in stone localization and clearance [32]. Treatment of mid-to-distal ureteral calculi has historically been avoided in children due to difficulties with localization over the sacroiliac joint and concern regarding possible injury to developing reproductive systems [43].

SWL success by stone composition is similar between the adult and pediatric populations [4]. Cystine stones are uniquely challenging due to their durability and high recurrence rates. While SWL monotherapy has demonstrated variable results in adults, there are few reports in the pediatric population. In a small recent series, Slavkovic *et al*. reported a 50% stone-free rate in

six children with cystine stone burden ranging from 0.2 to 2.5 cm. Although stone-free rates were low, fragmentation was achieved in 100% of patients and stone dissolution was achieved with medical therapy in the remaining children following SWL [53]. Authors have proposed that cystine stones formed within 2 years of therapy may be more easily fragmented with SWL and that stone number and not diameter may be more predictive of success [42].

Limitations and concerns

In children there is currently no consensus regarding the maximum size of residual stone fragments that are considered clinically significant [5, 42] and as a result there is no clear definition as to what constitutes "stone-free" status. While children have been shown to have a greater capacity to clear fragments then adults [54], the presence of residual fragments has been correlated with adverse clinical outcome [28]. Afshar *et al*. followed 26 renal units with residual fragments of 5 mm or smaller and reported that while 31% were asymptomatic with no fragment growth, 69% had adverse clinical outcomes, including fragment growth or clinical symptoms. Patients with residual fragments had a significant increase in adverse clinical outcome compared to stone-free subjects, and the presence of metabolic disorders was associated with fragment growth [28]. For these reasons, metabolic evaluations are now routinely being performed in children with a history of calculi and every attempt should be made to achieve a stone-free status. It is currently unclear if placement of a ureteral stent prior to SWL facilitates fragment passage and improves stone-free outcomes. Although prestenting rates are not consistent across series, current relative indications include cases of solitary kidneys, staghorn calculi, large ureteral calculi, obstruction, or abnormal anatomy, and are not based on total stone burden [4].

While SWL is well tolerated in children with few complications, stone-free rates following single-session monotherapy remain as low as 44% [34]. As a result children are subjected to multiple treatments requiring general anesthesia [45], which is concerning since the effects of shock waves on renal tissue are unclear. Recent evidence from the adult population indicates that shock-wave therapy results in renal vessel vasoconstriction and that renal tubular injury and subcapsular hematoma from cavitation and shear forces are dependent on the kilovoltage applied [55]. In an important study examining the long-term consequences of SWL, Krambeck *et al*. reported an increased risk of hypertension and diabetes mellitus related to bilateral treatment, number of administered shocks, and treatment intensity in 340 adult patients with a mean follow-up of 19 years post SWL [56]. Although these results are concerning, differences between pediatric and adult populations and limitations inherent to a questionnaire-based retrospective study make application of these data in children difficult. Retrospective studies in children have reported encouraging data that SWL and PCNL do not result in renal morphologic or functional alteration measured by glomerular filtration rate (GFR) and serial DMSA functional studies [57], but to date long-term data are unavailable. Long-term prospective data are clearly warranted to eliminate confounding variables and to fully assess the risks of chronic damage from SWL to developing kidneys.

Percutaneous nephrolithotomy

The safety and efficacy of PCNL for large stone burdens in the adult population have been well established [58]. Initial concerns with PCNL in children included the use of large instruments in pediatric kidneys, parenchymal damage and its potential effects on renal function, radiation exposure with fluoroscopy, and the risks of major complications, including sepsis and bleeding [43]. However, with increasing experience [35, 59–65] (Table 65.2), success rates utilizing PCNL as monotherapy or in combination with SWL (sandwich therapy) ranging from 68% to 100% have been reported [35, 66]. Although there is no current international consensus, relative indications for PCNL as primary therapy in children include large upper tract stone burden (>1.5 cm), lower pole calculi greater than 1 cm, concurrent anatomic abnormality impairing urinary drainage and stone clearance, or known cystine or struvite composition [5, 42].

Initially described in children by Mor *et al*. in 1997 [67], early pediatric PCNL series described the use of adult-sized instruments. Although initial series avoided performing PCNL in very small children (<5 years of age) due to concerns regarding parenchymal damage, recent data have suggested that PCNL is possible in very young children using adult-sized equipment and access tracts as large as 30F [60, 62, 64, 68, 69]. Despite these successes, early efforts focused on developing technology to minimize percutaneous tract size without affecting PCNL efficacy. Jackman *et al*. developed a novel percutaneous access technique ("mini-perc") using an 13F peel-away vascular access sheath and reported an 85% stone-free rate for 11 procedures in seven children with a mean age of 3.4 years [70]. The benefits of minimal tract dilation include increased maneuverability, decreased blood loss, and shorter hospital stay. However, theoretical limitations, including prolonged operative times and impaired visualization from bleeding, imply that this technique may not be adequate for very large stone burdens [43]. Recent advances in instrumentation, such as smaller nephroscopes (15–18F), balloon dilation

catheters, and more efficient energy sources for intracorporeal lithotripsy, have greatly facilitated percutaneous treatment techniques. As a result, open surgery has largely been supplanted by PCNL as the treatment of choice for large stone burdens in children of all ages.

Technique in children

Prior to PCNL, all films must be thoroughly reviewed to determine if the patient's stone burden is amenable to a percutaneous approach. The risks of PCNL must be completely discussed with the consenting parent or guardian. It must be understood that a percutaneous procedure carries risks that are not limited to but include bleeding requiring transfusion, delayed renal hemorrhage requiring angioablation, sepsis, pneumothorax, hemothorax, urothorax, incomplete stone treatment, and injuries to organs adjacent to each respective kidney. A urine culture 2–3 weeks prior to an elective procedure is mandatory in every pediatric patient, and every attempt should be made to treat preoperative urinary tract infections and minimize asymptomatic bacteriuria prior to therapy. In some cases, including children with complex anatomy or pre-existing stent/nephrostomy tube placement, even with a negative preoperative culture, 3–5 days of antibiotic prophylaxis may be warranted. In all cases, broad-spectrum intravenous antibiotics should be administered perioperatively (see above).

All percutaneous procedures are performed using general anesthesia and antibiotic prophylaxis. A warm operating room, body-temperature isotonic irrigant, brief anesthetic induction, short operative times, proper draping, and monitoring of body temperature should decrease the incidence of hypothermia and hyponatremia [43]. After induction of anesthesia with the patient in the lithotomy position, a retrograde pyelogram is performed to outline the collecting system and an occlusive balloon catheter is left *in situ* (Figure 65.1). The patient is then repositioned in the prone position with the torso elevated at 30° from the table surface with a towel roll [42]. Circumstances that require special consideration involve children with spinal anomalies such as spina bifida. In these patients, positioning can be a challenge due to existing spinal hardware and limb contracture [71]. Patients who have had prior spinal surgery consisting of vertebral fusion or Harrington rod placement will have restricted spinal mobility, spinal curvature, and/or atrophic or contracted extremities. Assessing the degree of mobility in the trunk and extremities is crucial in planning for PCNL in these patients. These patients must be placed in the most comfortable position possible without excessive contortion or flexion of the joints (Figure 65.2). In addition, as a result of spinal curvature, renal anatomy is altered and the risk of visceral injury and pneumothorax with percutaneous access is increased. Special attention must be paid to latex precautions in the myelomeningocele population

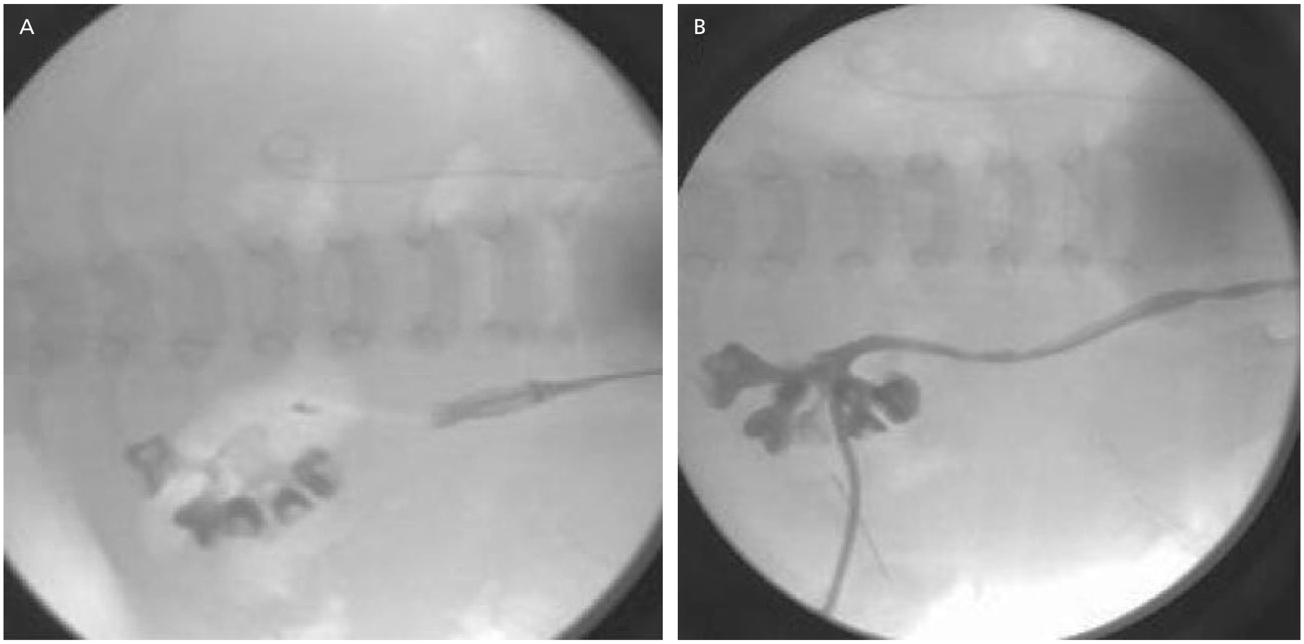

Figure 65.1 (A) Retrograde pyelogram showing a filling defect from a partial staghorn calculus in a 22-month-old male awaiting small bowel transplant for congenital tufting enteropathy. (B) Antegrade nephrostogram following "mini-perc" nephrolithotomy demonstrating clearance of the stone and patency of the ureter.

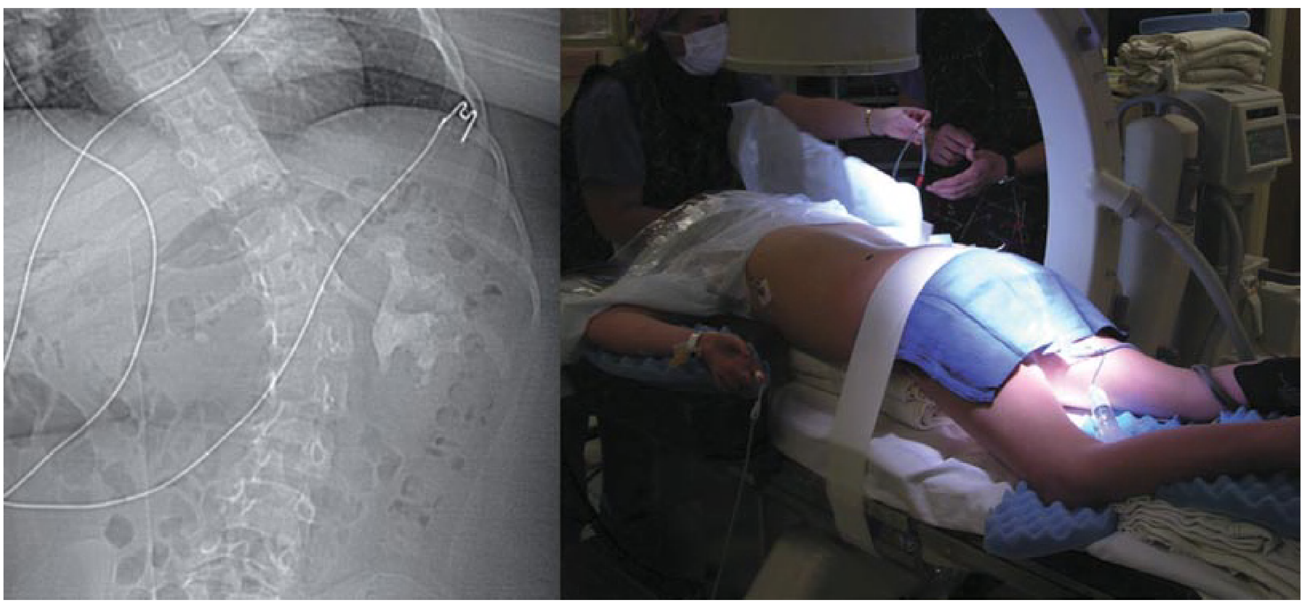

Figure 65.2 Spinal curvature prevents optimal positioning in a 10-year-old female patient with spina bifida undergoing percutaneous nephrolithotomy for a left complete staghorn calculus. As a result of spinal curvature and/or reconstruction, renal anatomy can be altered, increasing the risk of visceral injury and pneumothorax with percutaneous access. In these complex cases, extreme care must be taken to pad all joints in the prone position.

and, as in all cases, proper padding of pressure points is mandatory.

After selection of the desired calyx with the assistance of fluoroscopy in two planes, a 16G or 18G spinal needle is placed in the 30º position. The ideal tract is one that provides the shortest and most direct access to the stone. For complex calculi occupying multiple calyces including the lower pole, a supracostal posterior access is preferred to provide visualization of the superior calyx and pelvis, access to the pelvis and ureter, and straight access

Figure 65.3 (A) "Mini-perc" access technique utilizes a 13F x 11.5-cm peel-away vascular access sheath with an exposed trocar length of 1 cm (Mini-PERC™, Cook Medical Inc, Bloomington, IN, USA).. Insertion of the sheath into the collecting system can be performed with a single pass over an access wire and does not require sequential or balloon tract dilation, facilitating placement of a flexible cystoscope or ureteroscope for stone fragmentation and clearance (reproduced courtesy of Cook Medical Inc). (B) As an alternative to using sequential dilators in larger children, balloon dilation (X-Force™ N30 Nephrostomy Balloon Dilation Catheter; Bard Medical, Covington, GA, USA) of the nephrostomy tract permits dilation and sheath placement in a single step, thereby minimizing potential parenchymal trauma and bleeding (reproduced courtesy of Bard Medical Division).

to the inferior calyces, allowing easier manipulation of the working instruments and minimizing torque on the collecting system [72]. Following initial puncture, no attempt should be made to redirect the needle while it is located within the cortex of the kidney to avoid trauma. After access is confirmed with urine or irrigation return, a flexible guidewire is placed into the collecting system through the needle and directed down the ureter into the bladder. A small skin incision is made with a No. 11 scalpel, and 8F and 10F coaxial dilators are passed over the guidewire into the collecting system. Once in place, an Amplatz Super Stiff™ guidewire (Boston Scientific, Natick, MA, USA) is placed as a working wire.

Tract dilation can be performed by several techniques. Serial dilation with Amplatz dilators over working wires and subsequent sheath placement under fluoroscopic guidance is the most common technique employed. Alternatively, a 13F peel-away sheath (Docimo Mini-Perc, Cook Urological Inc, Spencer, Indiana, USA) and trocar are passed over the wire into the calyx under fluoroscopic guidance and the trocar is removed (Figure 65.3A). We have also had success using balloon dilators for nephrostomy tract dilation (Figure 65.3B). This technique permits dilation and sheath placement in a single step, thereby minimizing potential parenchymal trauma and bleeding from sequential dilation with metal dilators. While the decision to proceed with mini-perc or dilation is individualized based on child's age, anatomy, and stone burden, familiarity with all of the above techniques facilitates complete access with minimal morbidity.

Once access is obtained, nephroscopy and nephrolithotomy can be performed with a variety of energy sources for stone fragmentation. The outer diameter of nephroscopes range from 17F to 26F and a 15F flexible nephroscope with a 6F working channel has also been developed (Figure 65.4). In addition, 7F and 8F offset cystoscopes with 5F working ports and 7–9F flexible ureteroscopes can be used through an 11F access sheath with enough clearance to allow low pressure irrigation [5]. Energy sources currently utilized include ultrasonic lithotripsy, electrohydraulic lithotripsy (EHL), and the holmium laser, although individual preference is determined by availability and surgeon experience. Postoperative stenting and/or placement of a nephrostomy tube are both patient and surgeon dependent and vary between series. Similar to adult procedures, tubeless PCNL has theoretical advantages, including decreased postoperative pain and a short hospital stay, but currently data are limited in the pediatric population [73].

Outcomes

Recent large retrospective series of PCNL monotherapy have demonstrated high efficacy rates approaching 90% [60, 61, 68]. In 56 children with a mean age of 9.1 years and a mean stone burden of 337.5 mm^2, Desai *et al*. reported a stone-free rate of 89.8% utilizing EHL through a 14F nephroscope and a 20–24F sheath. Of these, 61% required multiple tracts and 45% were staged procedures. They reported that the number and size of tracts were significantly associated with postoperative hemoglobin decrease and overall transfusion rate (14%) [61]. In 52 children with a mean age of 7.9 years and a mean stone burden of 282 mm^2, Zeren *et al*. reported an 87% stone-free rate using ultrasound and EHL for fragmentation and tract dilation from 18F to 30F. While prevalent

in the electronic edition

Figure 65.4 The 20.8F Percutaneous Universal Nephroscope has a large (14F) oval working channel that accommodates instruments up to 3.5 mm in diameter, including the standard ultrasonic lithotripters, while allowing for effective irrigation (top). The 15/18F Miniature Nephroscope is ideal for "mini-perc" procedures, as it can be used with access sheaths as small as 13F. It has an offset eyepiece and a 6F working channel (bottom) (reproduced courtesy of Richard Wolf).

complications included postoperative fever (30%) and need for transfusion (24%), transfusion was significantly associated with operative time, sheath size, and stone burden [60]. In 135 children aged 8.9 years with a mean stone burden of 507 mm^2, Salah *et al*. reported a 98.5% stone-free rate utilizing ultrasound through a 26F nephroscope. Complication rates were low (8% urine leak, 0.7% transfusion), with only one patient requiring a second procedure [62]. In a recent series of 46 children with a mean stone burden of 332 mm^2, Bilen *et al*. reported an 88% stone-free rate using EHL, ultrasound, and the holmium laser. When stratified by tract size (14, 20, and 24F), efficacy rates were similar in all groups, but there were no complications or transfusions in the 14F tract group [68]. Similar to the adult population, these large series utilizing primarily adult-sized instruments demonstrate that both stone clearance efficacy and transfusion rates are related to the size and number of access tracts utilized [74].

In an effort to reduce the number of tracts and associated morbidity, some centers advocate the use of primary PCNL with adjunctive SWL therapy to clear residual stone fragments, although this has largely fallen out of favor in the adult population [75]. In a small series of 29 children with a mean age of 3.8 years and a mean stone burden of 2.4 cm, Mahmud *et al*. reported a 60% stone-free rate after PCNL monotherapy using EHL through a 17F angled nephroscope. A single tract was utilized in all patients, and after SWL sandwich therapy the stone-free rate increased to 100% [66]. In a larger series of 169 children with a mean stone burden of 3.1 cm, Samad *et al*. reported a 59% monotherapy stone-free rate with 96% of cases performed through a single tract. Approximately one-third of primary failures were treated with SWL; the cumulative stone-free rate in all patients was 93.8% with a 3.6% transfusion rate [64]. When stratified by age, anatomy, bilaterality, and renal function, stone-free outcomes were equivalent in all groups. The decision to follow PCNL with SWL is related to operator experience with percutaneous technique and available technology, and is largely utilized outside of the USA. At our institution, our preference is to perform a second-look nephroscopy through the original tract to ensure stone-free status during the initial hospital admission rather than progress to SWL sandwich therapy. Endoscopic surveillance during the initial procedure can determine the need for second-look nephroscopy without relying on additional imaging and the associated risks of radiation exposure [76]. Following our adult endourologic counterparts, we anticipate that further developments in technique will include adoption of tubeless techniques, supine positioning, and modifications to facilitate smaller nephroscopy access tracts. New-generation smaller rigid nephroscopes with improved optics should optimize visualization for stone clearance with the potential to minimize tract size and postoperative morbidity [4]. Technically challenging in nature, surgeon experience with PCNL is paramount in developing individualized treatment plans to optimize efficacy with minimal morbidity [43].

Ureteroscopy

Adoption of URS for the treatment of pediatric stone disease has lagged behind that of adults due to concerns regarding use of large ureteroscopes in small-caliber ureters, a higher post-SWL stone fragment clearance rate compared to adults [54], and the low incidence of stone formation in children. Since the mid 1980s, with the acceptance of SWL as primary therapy for upper tract calculi of less than 1.5 cm, URS has been historically utilized for calculi below the iliac crests, and for upper tract calculi after SWL failure [5]. URS was not considered primary therapy for upper tract stones in children due to concern for ureteral ischemia, perforation, stricture formation, and development of VUR as a result of dilation of small-caliber ureteral orifices [43].

With significant improvements in both the miniaturization and durability of endoscopic equipment and the widespread acceptance of the holmium laser, URS has become a more attractive option in young children [4]. First described by Ritchey *et al*. in 1988 [77], early series utilizing rigid URS for distal ureteral stones reported stone-free rates ranging from 86% to 100% with low complication rates [25, 35, 78–81]. In a comparison of 31 children randomized to URS or SWL as primary therapy for distal ureteral stones, De Dominicis *et al.* reported a significantly higher stone-free rate after one treatment (94% vs 43%) for children treated with URS [79]. Results from these retrospective studies provide evidence refuting the notion that dilation of the pediatric ureter will result in VUR or the development of ureteral strictures. Supporting this notion, a systematic review of the literature evaluating 221 early pediatric ureteroscopies, Schuster *et al*. noted only two ureteral strictures and a minimal incidence of VUR [78].

Early successes with treatment of distal calculi in children [82–84] have led to a number of centers expanding its utility to the treatment of upper tract calculi (Table 65.3). Results for our institution's and other tertiary care centers' early experiences have demonstrated stone-free rates between 88% and 100%, with complication rates similar to those of the adult population [81, 85–91]. Lesani *et al*. reported their experience using 4.5F, 6F, and 8F rigid URS in treating proximal ureteral stones in 24 children with a mean age of 10.7 years. They did not perform ureteral dilation in any cases, and 100% of children were rendered stone free [85]. In a large series of 100 children with a mean stone diameter of 8.3 mm, 52% of which had upper tract calculi, Smaldone *et al*. reported a 91% stone-free rate, with 9% of children undergoing staged procedures. With a mean follow-up of 10 months, they reported a 4.2% perforation rate managed with ureteral stenting and one distal ureteral stricture requiring open neocystostomy [86]. Corcoran *et al*. reviewed their cohort of 47 children (mean age 9.4 years) with upper tract calculi managed with flexible URS and holmium laser lithotripsy. With a mean stone burden of 10.2 mm, they reported an 88% stone-free rate, with 26% requiring staged procedures [87]. In the largest series to date, Kim *et al*. reported their results in 167 children undergoing 170 flexible URS treatments. Choosing to prestent to allow passive dilation in 95 children (57%) in whom retrograde access could not be obtained, they reported 100% stone clearance for stone burdens of 10 mm or less and 97% for stone burdens greater than 10 mm (mean stone burden 6.1 mm) [90].

As the indications for URS in children continue to expand, acceptable stone-free rates have been reported for increasingly large stone burdens. In 23 children with a mean stone size of 17 mm, Dave *et al*. reported stone-free rates of 75% for renal pelvis calculi and 100% for polar stones. However, in seven children with partial staghorn stones, the stone-free rate was only 14%, implying that complex stone burdens involving more than one calyx may be more amenable to PCNL [89]. Supporting this notion, a recent report observed that 71% of upper tract calculi greater than 10 mm in diameter required more than one procedure to achieve stone-free status [91], indicating that there still is room for improvement in the URS management of the upper tract. Adoption of techniques utilized in the adult population, most notably sequential coaxial and balloon dilation of the ureteral orifice and use of ureteral access sheaths, may facilitate the treatment of larger stone burdens during a single session [43]. Initially described in eight children by Singh *et al*. [92], ureteral access sheaths have been shown to facilitate repetitive upper tract access, reduce intrarenal pressures, decrease operative time, and improve stone-free rates in adults [93]. In our experience, use of ureteral access sheaths and the 6.9F flexible ureteroscope has made possible treatment of lower pole calculi that would have previously required SWL or PCNL. Cannon *et al*. reported a 76% stone-free rate in 21 children with lower pole calculi and a mean stone diameter of 12.2 cm. After a mean of 11.4 months, no major complications were observed [88]. With the transition from SWL to URS as a primary treatment modality at our institution, current relative contraindications to URS management include staghorn stones in recurrent stone formers more amenable to PCNL, anatomic anomalies making retrograde access difficult, and previous endoscopic failure [86].

Technique in children

All URS procedures are performed under general anesthesia to prevent patient movement and minimize the risk of ureteral perforation. Demonstrating sterile urine is mandatory in all patients preoperatively, particularly in patients with indwelling ureteral stents. Following antibiotic prophylaxis, patients are placed in the lithotomy position and rigid cystoscopy (7.5F, 11F, or 18F) is performed to place a safety or working wire. Under fluoroscopic guidance, the guidewire is advanced into the renal pelvis or beyond the level of the stone. Ureteral orifice dilation is performed with 8/10F coaxial dilators (Boston Scientific) in ureters that have not been prestented, or when the rigid/flexible ureteroscope cannot easily be advanced. We generally do not use balloon dilation of the ureteral orifice due to concern for the development of ureteral stricture from ischemia. Our bias is that use of the 8/10F dilator allows for tactile feedback regarding the tightness of the ureter, which is not available with balloon dilation. If we encounter difficulty with the 8/10F dilator, our preference is to place a stent and return for a second procedure rather than to dilate more aggressively [43].

The decision to use a flexible or semi-rigid (6.5–7.5F) ureteroscope depends on size and location of stone, anatomic factors, and individual surgeon preference. A 4.5F rigid ureteroscope is also currently available for use, although our experience with this device is limited (Figure 65.5A). As a general rule, the working port of most ureteroscopes ranges from 2.4F to 3.5F in semi-rigid models and 1.8–3.5F for flexible models. Tip deflection of up to 270° can facilitate access to lower pole calculi, but as in adult patients, difficulty exchanging instruments through the working element of a maximally deflected flexible ureteroscope can limit its effectiveness in some settings (Figure 65.5). Rigid or semi-rigid URS is routinely performed with a safety wire in place, while flexible URS is performed with both safety and working wires in place. Ureteral access sheaths (internal diameter of 9.5F or 12F) are utilized to facilitate flexible URS in cases of large proximal ureteral

Figure 65.5 (A) Pediatric semi-rigid self-dilating ureteroscopes (4.5F/6.5F "Needle" Ureteroscope; Richard Wolf Medical Instruments Corp, Vernon Hills, IL, USA) may be used for rigid ureteroscopy even in toddlers. A 4.5F distal beak allows easier passage to facilitate dilation with the 6.5F proximal component (reproduced courtesy of Richard Wolf Medical Instruments Corp). (B) Technical modifications in newer generation flexible ureteroscopes (AUR™-735 Flexible Pediatric Ureteroscope; Gyrus ACMI LP, Maple Grove, MN, USA) permit direct visualization and access to the entire pediatric collecting system. Small diameter graduated design (7.2F at tip), dual deflection capabilities (160° down deflection, 120° up deflection), advanced fiberoptics, and larger working channels (3.6F) facilitate upper tract access even in tortuous ureters (reproduced courtesy of Gyrus ACMI).

or renal pelvis stone burdens (Figure 65.6). Irrigant, which may be used under pressure, should be isotonic and at body temperature to avoid hypothermia and hyponatremia. Calculi are extracted with a basket when feasible or fragmented using the holmium:YAG laser to facilitate removal. Other energy sources for fragmentation include ultrasound lithotripsy and EHL. The decision to place a ureteral stent postoperatively is based on the duration of the procedure, number of passes with the ureteroscope, and degree of visible ureteral trauma or edema at the conclusion of the procedure [43]. If the patient can tolerate leaving a urethral string in place for 3 days to 1 week, the patient's parents are asked to remove the stent at home; otherwise the stent is removed under brief anesthetic after 7 days.

Concerns and limitations

With smaller, more durable ureteroscopes and improved optics for visualization, URS is becoming more prominent in the pediatric endourologists armamentarium of stone management techniques. However, many unanswered questions still need to be addressed. Concerns for unrecognized ureteral trauma include mucosal flaps and tears, creation of a false passage, perforation, and partial-to-complete avulsion. An injury can occur while dilating the ureteral orifice, introducing the ureteroscope, or during antegrade/retrograde passage of guidewires or baskets, and it is imperative that these injuries be recognized promptly to minimize long-term sequelae. Should a traumatic injury be recognized, immediate discontinuation of the procedure with passage of a ureteral stent is paramount to reduce further ischemic damage and extravasation of irrigant/urine.

In postpubertal children with an adult body mass, URS access is technically similar to the adult population. In the small prepubertal child, questions remain regarding whether to attempt primary treatment without ureteral orifice dilation, perform dilation at the time of definitive therapy, or place a stent and allow the ureter to passively dilate prior to definitive therapy. In 29 children with a mean age of 11 years, Herndon *et al*. performed semi-rigid URS with 4.5F and 6.5F ureteroscopes for distal ureteral calculi. Fourteen percent of the children were prestented, but no child was actively dilated. The ureter was accessed in 100% of cases and the stone-free rate was 96% [94]. Since our flexible and semi-rigid ureteroscopes are 6.9F and 7.5F, respectively, it is our preference to sequentially dilate with the 8/10F coaxial dilator even in very young children, but if we encounter difficulty, a stent is placed rather than dilating more aggressively [43]. While we feel this approach minimizes long-term complication rates, particularly in the management of upper tract calculi, it increases the

Figure 65.6 (A) Placement of a ureteral access sheath (Flexor®, Cook Medical Inc, Bloomington, IN, USA) provides a continuous working channel (internal diameter ranging from 9.5F to 14F, length ranging from 13 to 55 cm) for the repeated atraumatic introduction of endoscopes and instruments when treating large upper tract stone burdens (reproduced courtesy of Cook Medical Inc). (B) A 1-cm left lower pole calculi in a 16-year-old patient. Following ureteral orifice dilation, a ureteral access sheath (14F internal diameter, 16F external diameter, 35 cm length) is advanced over a guidewire past the pelvic brim. (C) Gaining access to the proximal ureteral (white arrow) facilitated repeat access to the lower pole for stone fragmentation and clearance (black arrow).

number of children who require a second anesthetic and procedure to achieve stone-free status. Our recent finding that 40% of pediatric patients will require at least two procedures to treat upper tract calculi ureteroscopically suggests that with current equipment, the likelihood of achieving a stone-free state after one URS procedure may not be significantly better than with SWL [87]. Another area of contention is the necessity of placing a post-URS stent in all children. While the tendency in large series has been to leave a stent in place after URS manipulation in a majority of children [86], some authors have reported no acute or long-term sequelae despite leaving a post-URS stent in less than 20% of cases [87]. In our practice, a decision to leave a stent is made on an individual patient basis and is based on surgeon preference as well as the degree of visible ureteral trauma at the conclusion of the procedure.

Laparoscopic and robot-assisted pyelolithotomy

Treatment of large stone burdens in children is technically challenging, often requiring multiple procedures. Laparoscopy and robot-assisted laparoscopy has been utilized successfully in adults for the treatment of calculi during the concomitant treatment of ureteropelvic junction obstruction (UPJO) and in the primary treatment of staghorn calculi. Small series utilizing these techniques in children have only recently been described. In eight children (mean age 4 years) with a mean stone burden of 2.9 cm undergoing transperitoneal laparoscopic pyelolithotomy, Casale *et al*. reported a 100% success rate, a mean hospital stay of 2.15 days, and a mean operative time of 1.6 h, with no major complications [95]. In the first report of robot-assisted laparoscopic

pyelolithotomy, Lee *et al*. described their experience in five patients; four with cystine staghorn calculi refractory to PCNL and SWL and one with calcium oxalate calculi and concurrent UPJO. Of these cases, four were completed robotically, with one patient having a residual 6-mm lower pole stone and one requiring conversion to an open procedure. Mean operative time in this series was 315 min, mean estimated blood loss was less than 20 mL, and mean hospital length of stay was 3.8 days [96]. These early experiences demonstrate that laparoscopic pyelolithotomy is feasible, safe, and efficacious as an alternative to open pyelolithotomy in children, and warrants further study. However, due to their demanding technical nature, these procedures will likely be limited to endourologic management failures in academic centers with abundant expertise in laparoscopic and robotic pediatric surgery [43].

Management of bladder calculi

Bladder stones are more often found in children from developing countries, are composed of ammonium urate, and are thought to be related endemically to malnutrition [5, 97]. In contrast, among children from industrialized nations, bladder stones are most often found in those with spinal cord injuries and/or congenital abnormalities such as spina bifida. Very often these children have undergone augmentation cystoplasty and/or manage their bladders by clean intermittent catheterization. It has been reported that up to 50% of those children with reconstructed bladders will develop a bladder stone(s) in their lifetime, the majority of which are of struvite composition [98]. Authors have postulated that urinary stasis, bacterial colonization or infection with urea-splitting organisms, retained mucous, and foreign bodies are all contributing factors to the formation of bladder stones in these complex children [5].

Historically, open cystolithotomy has been the treatment of choice in the management of bladder calculi. Transurethral cystolithotripsy is an alternative, but it is not ideal in many children due to their smaller caliber urethra or previous bladder neck reconstruction. Percutaneous cystolithotripsy, however, is now utilized worldwide with advantages including shorted hospital stay, improved cosmesis, and a reduction in indwelling catheter duration postoperatively [99]. Currently, percutaneous cystolithotripsy has evolved into the preferred method to treat bladder stones that have formed in naïve and reconstructed bladders alike [100]. In 155 children (mean age 4.5 years) with a mean bladder stone burden of 2.3 cm, Salah *et al*. reported excellent success rates with minimal morbidity utilizing a 26F nephroscope and 30F access sheath introduced through a 1-cm suprapubic incision [101]. A successful modification of this technique utilizing a 16F peel-away sheath and a ureteroscope has been reported even in very young children without negative sequelae [102].

Percutaneous cystolithotripsy in children may be performed under ultrasound or fluoroscopic guidance and is often completed as an outpatient procedure. Depending on imaging preference to aid obtaining access, the bladder is first filled to capacity with water or contrast. The child is placed in the Trendelenberg position to minimize the risk of bowel injury during percutaneous access and tract dilation. An 18G needle

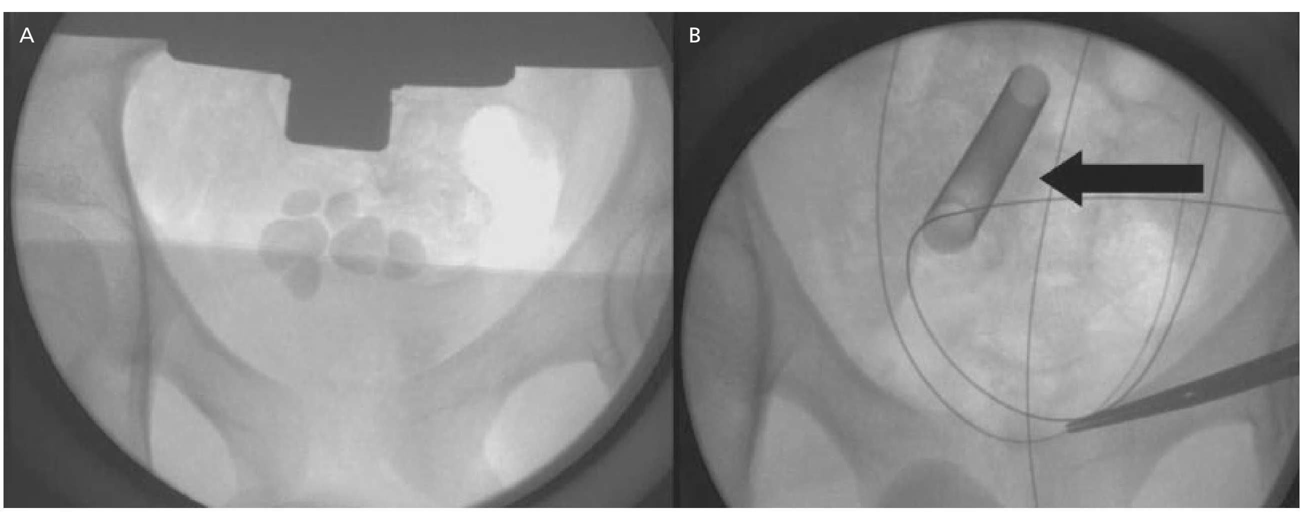

Figure 65.7 (A) A 12-year-old male with a history notable for spina bifida and ileocystoplasty was found to have multiple large bladder calculi on a work-up for recurrent *Proteus mirabilis* infections. (B) Successful percutaneous cystolithotripsy with an ultrasonic lithotripter was performed through a 30F access sheath (arrow).

is placed into the distended bladder in the midline, one to two finger breadths above the pubic bone. Once proper placement is confirmed with return of fluid, a guidewire is passed under fluoroscopic guidance. Similar to percutaneous renal procedures, the size of the access tract is based on the relative stone burden and size of the child (Figure 65.7). In our practice, a 26F nephroscope is used to extract stones of less than 1 cm with a rigid stone forceps or an ultrasonic lithotripter may be used to fragment stones of greater than 1 cm. For very large stone burdens, calculi can be placed in an EndoCatch™ bag (Covidien, Norwalk, CT, USA) prior to fragmentation to facilitate lithotripsy and fragment removal. At the procedure's conclusion, a Foley catheter is left per urethra or a continent catheterizable stoma for 1 week, and the rectus fascia defect is closed with a 2-0 vicryl stitch. Complications are uncommon but include persistent urine leak, bowel injury with access, and damage to the ureteral orifices. Post-operative antibiotic use is variable and depends on preoperative urine cultures, degree of bladder inflammation, or presence of grossly infected urine, and previous urinary tract reconstruction.

Determination of stone-free status

As the surgical management of pediatric stone disease evolves, the lack of a consistent definition of "stone free" following definitive therapy is an issue that remains unaddressed. Although controversial, in select adult patients all stone fragments can be considered clinically significant and can lead to stone recurrence [103]. Likewise, the presence of residual stone fragments in children has been associated with poor outcomes [28], and any size stone fragment in a young stone former may result in the need for repeat surgical procedures. However, these fragments often are not detected on ultrasound or kidney, ureter, bladder (KUB) images, necessitating reliance on CT imaging in select children.

Balancing the risks of radiation exposure for post-treatment stone detection and the risks of anesthesia for secondary procedures is a challenging dilemma for contemporary pediatric endourologists. Newer, high-speed helical CT scanners reduce radiation exposure and rarely require intravenous sedation. In addition, maximizing intraoperative fragment detection by direct visualization in URS and PCNL, and continued development of high -resolution realtime fluoroscopy may result in less reliance on postoperative imaging and decrease the need for second-look nephroscopy/URS, SWL, or sandwich therapy [104]. Until the risks of radiation exposure in children are more clearly defined, surveillance in these children will be individualized based on age, anatomy, stone burden, and underlying metabolic abnormalities [43].

Endourologic management of ureteropelvic junction obstruction

Whitaker test

Diagnosis of the asymptomatic dilated upper tract remains a clinical management challenge. Introduced in 1973, the Whitaker test was developed as a means of diagnosing renal obstruction by directly measuring renal pelvis pressures. The Whitaker test is performed by gaining percutaneous access to the upper tract and placing a Foley catheter to decompress the bladder. With the patient in a prone or semi-prone position, contrast is infused into the renal pelvis at a rate of 10 mL/min. The relative renal pelvis pressure is then calculated by subtracting the measured renal pelvis pressure from the bladder pressure [105]. Relative renal pelvis pressures greater than 22 cmH_2O are defined as obstructed, 15–22 cmH_2O as equivocal, and less than 15 cmH_2O as unobstructed. However, the role of the Whitaker test in the evaluation of hydronephrosis remains controversial. Arguments against point to its invasive nature, large range of equivocal results, super physiologic flow rates (<10 mL/min), and the impact of renal pelvis compliance on test results [106]. Supporters point to its ability to provide realtime information on the collecting system, and to evaluate collecting systems with decreased renal function and those with equivocal findings on renal scintiography [107].

Renal tissue tracer transit time, pressure flow measurements, and Doppler sonography have all been developed as a means of identifying and quantifying upper tract obstruction, but a gold standard has yet to be found. Wahlin *et al*. recently reported their observations in 46 children aged 5–6 months to 12 years of age with hydronephrosis who underwent upper tract pressure flow studies and a Whitaker test prior to pyeloplasty. After identifying 37 patients with obstructed systems, they reported that the pressure flow studies were superior to the Whitaker test by quantifying a value for the degree of obstruction. While the Whitaker test did not provide quantification of obstruction, it confirmed obstruction in 95% of patients, demonstrating its validity as a diagnostic tool in select pediatric patients [106].

Lupton *et al*. recently published a series of 145 adult patients who underwent Whitaker testing over a 25-year period. When compared with diuretic renography, the Whitaker test recharacterized 41% of studies originally interpreted as obstructed systems to be unobstructed, and was able to classify 70% of radiographically "equivocal" systems as obstructed or unobstructed. Based on their results, they advocate the use of a Whitaker test as an adjuvant investigation when there is evidence of obstruction with poor renal function, equivocal results from noninvasive studies with a high

clinical suspicion for obstruction, and evaluation of flank pain with an unobstructed renogram [108]. While, there are limited data to support routine use in the pediatric population, it will likely continue to be a useful adjunct study in the small subset of patients whose upper tract obstruction is unable to be fully evaluated by noninvasive means.

Endopyelotomy

Despite its widespread use in the adult population, it was not until the late 1990s that endopyelotomy was evaluated in the pediatric population. Principally based on the intubated ureterotomy, the stenotic or strictured UPJ is incised longitudinally with a holmium laser or cautery/balloon dilation in a full thickness manner via an antegrade or retrograde endoscopic approach, and allowed to heal over a ureteral stent [109]. Initial reports demonstrated encouraging success rates; however, these results were from small cohorts with limited follow-up. In addition, children undergoing antegrade endopyelotomy often required a nephrostomy tube and/or nephroureteral stent and their care was associated with a greater overall cost [110]. In 2004, Tallai *et al*. reported outcomes in 37 children (mean age 11.5 years) undergoing antegrade endopyelotomy over a 12-year period. Despite an overall success rate of 89%, two children required exploration, ligation of the bleeding crossing vessel, and open dismembered pyeloplasty due to postoperative hemorrhage. There were also two children representing with postoperative pyonephrosis who ultimately required nephrectomies[111].

With documented superior success rates of open pyeloplasty even in very young children [112], the indications for endopyelotomy in pediatric patients remain controversial [113]. In addition, with emerging data to support the safety and efficacy of laparoscopic pyeloplasty in children as young as 6 months of age [114], there is minimal evidence to support endopyelotomy as a primary intervention for management of pediatric UPJO. In the adult population, endopyelotomy has been advocated as a salvage therapeutic option after failed pyeloplasty [115]. Initial data have supported the use of endopyelotomy for this indication in children, but current recommendations support its use only when the ureteral lumen is recognizable for cannulation [116]. Relative contraindications include a large collecting system, poor ipsilateral renal function, and the presence of anomalous crossing renal vessels [109, 117], but these also remain controversial [118]. Braga *et al*. recently compared success rates between retrograde endopyelotomy and redo pyeloplasty in 32 children who had failed primary pyeloplasty. With a mean follow-up of 47 and 33 months, respectively, endopyelotomy was only successful in 39% of patients, while redo pyeloplasty was successful in 100% of patients ($P = .002$). Despite a limited number of patients, narrowed ureteral segment greater than 10 mm, and age younger than 4 years were associated with a poor outcome with an endoscopic approach [119]. Due to the potential morbidity and technical difficulty of redo pyeloplasty, the only contemporary relative indication for endopyelotomy in children is for recurrent UPJO following failed pyeloplasty, and even then only in select cases.

Conclusions

Evolution of technique and miniaturization of instruments have changed the management of pediatric stone disease. However, despite encouraging results, concern remains regarding the safety of endourologic treatment in smaller patients and its subsequent effects on the growing kidney. While SWL is still considered first-line therapy for upper tract calculi of less than 1.5 cm, evidence is accumulating that URS may be more efficacious in treating upper tract stone disease in children. While PCNL remains the most effective technique for large upper tract stone burdens, there are now reports of laparoscopic and robot-assisted laparoscopic pyelolithotomy in major pediatric academic centers with extensive laparoscopic and robotic experience. Prospective randomized studies designed to evaluate the endourologic management of upper tract calculi in children are sorely needed, and until these data are available, individual surgeon experience is the most important factor in determining the appropriate treatment modality. Similar to endourologic management in the adult population, familiarity with the full spectrum of endourologic techniques facilitates a minimally invasive approach to the entire pediatric urinary tract.

CHAPTER 66

Cost-Effective Strategies for Management of Renal and Ureteral Calculi

Sara Best, Yair Lotan & Margaret S. Pearle
Department of Urology, University of Texas Southwestern Medical Center, Dallas, TX, USA

Introduction

Nephrolithiasis is a common and costly disorder. Data from NHANES III (1988–1994) indicates a lifetime risk of stone disease in American adults of 5.2%, up from 3.2% in 1976–1980 [1]. Accordingly, in 2000 it was estimated that over US$2 billion was spent on the treatment of urolithiasis, a substantial increase from the US$1.37 billion spent in 1994, and almost certainly an underestimate. Indeed, the Urologic Diseases of America Project estimated that the average differential in annual expenditure for a privately insured individual between the ages of 18 and 64 years with or without a diagnosis of urolithiasis was US$4472 (US$7656 vs US$3184), a difference attributable to the cost of managing stone disease [2]. Furthermore, as the disease is most prevalent among individuals in their working years, it was estimated that among the 1% of working-age Americans who experienced a stone event in 2000, one-third of them each missed an average of 19 h of work due to this diagnosis [3]. These statistics underscore the substantial economic impact of nephrolithiasis on not only the individual, but also on the healthcare system and society.

Basics of cost analysis

With limited resources and numerous treatment options, physicians must be cognizant of the economic consequences of various treatment choices. Economic factors can impact availability of technology and feasibility of medication use to the extent that physicians need to consider both the cost and effectiveness of various treatment options. To understand cost analyses in the literature, the relevant language must first be clarified. The definition of "cost" varies according to whose perspective is being considered. If cost is considered from the patient's perspective, it refers to the amount they can expect to pay out-of-pocket for a given treatment, which in turn depends on the type of insurance, associated co-pay/deductible requirements, and employment status, since income may be lost during treatment. Consequently, cost from the patient perspective is highly variable and must be individualized. For example, the cost shouldered by an uninsured, working individual who must pay all of their own healthcare bills out-of-pocket will be vastly different from the cost for a person living within a free, nationalized healthcare system. Furthermore, the decision to initiate a long-term medical prophylactic program to prevent future stone formation has a different financial impact from a strategy of periodic emergency room visits and surgery to treat stones as they arise.

Quantifying the societal cost of healthcare-related to nephrolithiasis is likewise problematic. In countries with a national healthcare system, medical decision-making directly impacts the nation's budget. In other countries, such as the USA, programs such as Medicare or Medicaid are funded by the government to cover the healthcare needs of select groups of patients, partially tethering the economics of healthcare to overall budgetary concerns. Throughout the world, indirect economic consequences, such as lost wages due to illness impact

Smith's Textbook of Endourology, Third Edition. Edited by Arthur D. Smith, Gopal H. Badlani, Glenn M. Preminger, Louis R. Kavoussi.

society as a whole, although these indirect costs are difficult to quantify.

Most research into healthcare cost takes the perspective of the hospital, since hospital costs and expenditures are easier to define, even though they may vary somewhat from center to center and from country to country. These costs consist of a variety of cost centers, including the purchase and maintenance costs of capital equipment such as lithotripters, the cost of physician and other healthcare workers' labor, medications, and services and supplies utilized during hospitalization (i.e. room and board, pharmacy, radiology).

Of note, in any discussion about the financial implications of a treatment strategy, the terms "cost" and "charge" must be distinguished. "Cost" typically refers to the direct cost to the hospital to purchase an item or provide a service, whereas "charge" includes not only the direct cost of an item/service, but also the indirect cost associated with its supply, such as administration and marketing, and a defined profit margin. The ratio of cost to charge may vary between surgical procedures; e.g. a hospital may elect to exact a larger profit margin from one service than another despite a lower actual cost to the hospital. The overall charge is what appears on the bill, although its components are often difficult if not impossible to sort out. Since hospital billing statements are often the most accessible cost data, charges are unfortunately frequently used in cost analyses reported in cost literature. It should be apparent after this discussion that charge data are somewhat arbitrary and may not relate in a consistent way to actual cost. Nonetheless, cost data are not without flaw either, as the amoratization of capital equipment, cost of reusable equipment, and specific labor costs can be nebulous.

Furthermore comparing costs of treatment across countries with different healthcare systems can be problematic. For example, the difference in costs of common procedures such as ureteroscopy (URS) and shock-wave lithotripsy (SWL) are highly variable among countries and depend on both the cost of the capital and disposable equipment as well as the degree of subsidization [4, 5]. As such, cost based on one center's situation may not be applicable in another healthcare system. Consequently, cost analyses must be viewed in the context in which they are presented.

Finally, it is important to mention that cost is only one of a variety of outcomes that should be considered when making medical decisions. Other factors affecting outcomes such as stone characteristics, patient comorbidities and preferences, equipment availability, and surgeon preference and skill may, in some cases, outweigh cost concerns in the selection of a treatment strategy for nephrolithiasis. While cost analyses often take into account efficacy since retreatments can be costly, the most efficacious option may not be the least costly, particularly when considering observation as a treatment option.

Ureteral calculi

The treatment of ureteral calculi is comprised of several decision points: how to make the diagnosis, what measures are used to ascertain the need for surgical intervention, and how to determine the optimal surgical treatment modality. Each option along the decision tree has associated cost concerns that impact the overall cost of any treatment strategy.

Diagnosis

The cost of treating ureteral calculi begins with diagnosis. Historically, intravenous urography (IVU) was the gold standard among imaging modalities for the diagnosis of ureteral calculi. However, the introduction of helical computed tomography (CT) provided a faster, more accurate diagnostic tool for the evaluation of acute flank pain, with a sensitivity of 98% and a specificity of 95–100% [6, 7]. Although the cost of CT is higher than the cost of IVU, it was theorized that the higher capital equipment cost associated with CT would be offset by the additional cost of further imaging studies should IVU fail to make a diagnosis.

Several studies have analyzed the cost of CT versus IVU in the setting of acute flank pain. Pfister *et al.* performed a prospective, randomized trial (RCT) comparing nonenhanced CT and IVU for acute flank pain and found equivalent direct charges (310 Euro vs 309 Euro, respectively), but with the caveat that the indirect cost associated with CT was likely lower because examination time for CT was only about 25% as long as for IVU [8]. Eikefjord *et al.* found a greater cost differential between CT and IVU (32 Euro vs 117 Euro, respectively), with the bulk of the cost savings for CT attributed to lower personnel costs related to shorter examination time [6]. Other studies have shown cost savings or cost-equivalence for CT over IVU [7, 9] and further showed that CT has the additional advantage of more frequently diagnosing the source of the pain when ureteral calculi were ruled out (62% for CT vs 22% for IVU) [6]. Based on higher sensitivity and lower cost, CT has become the imaging modality of choice for the diagnosis of acute flank pain. In the future, cost studies may need to consider not only the acute cost associated with CT but any potential risks associated with greater radiation exposure that may result in additional future expense.

Urgent intervention

With the definitive diagnosis of a ureteral stone, the need for urgent intervention must be entertained based

on the clinical setting. In the face of ureteral obstruction and suspected infection, urgent decompression of the collecting system is mandatory to prevent urosepsis and its sequelae. Both percutaneous nephrostomy and ureteral stent placement have been shown to be effective for temporary urinary diversion. The choice of optimal drainage modality for the obstructed kidney was addressed in two RCTs [10, 11]. Pearle *et al.* randomized 42 patients with obstruction and suspected infection due to ureteral calculi to either percutaneous nephrostomy or ureteral stent placement, and compared time to clinical improvement as well as cost [11]. Although the two modalities were equally efficacious with regard to the time to normalization of temperature and/or white blood count, percutaneous nephrostomy tube placement was the less costly of the two procedures (US$1137 vs US$2401, respectively), largely due to the use of general anesthesia in the operating room for stent placement. Mokhmalji *et al.* randomized 40 patients with hydronephrosis due to ureteral calculi, with or without signs of infection, to either nephrostomy or stent, and concluded that percutaneous nephrostomy was the superior drainage modality based on the need for less fluoroscopy time (10% vs 40% with >2 min, respectively), shorter time to definitive stone treatment (25% vs 50% with need for diversion at 2 weeks, respectively), and shorter duration of antibiotics (0% vs 64% requiring antibiotics for longer than 5 days, respectively) [10]. However, cost was not analyzed in this study.

An additional potential cost concern in favor of nephrostomy is the possibility of failed stent placement in some patients with obstructing stones. Percutaneous nephrostomy in the setting of obstruction and hydronephrosis is generally highly successful due to the large, dilated collecting system. Indeed, Mokhmalji *et al.* reported a 20% rate of failed stent placement in their series compared with no failed nephrostomies [10]. In contrast, Pearle *et al.* reported no unsuccessful stent placements but a single unsuccessful nephrostomy tube placement [11]. Although several series have reported rates of successful stent placement of approximately 80% [10, 11], stent failures will incur the additional cost of salvage nephrostomy.

Presuming equivalent efficacy for collecting system decompression in the acute setting of obstruction and infection, the choice of nephrostomy versus stent placement can be based on secondary factors such as cost, availability of an operating room or an interventional radiologist, location or size of the stone, and patient and physician preference.

Medical expulsive therapy

The likelihood of spontaneous passage of ureteral calculi depends on stone size, stone location, and ureteral anatomy [12, 13]. Spontaneous passage rates vary inversely with stone size and increase the more distally in the ureter the stone is located at the time of diagnosis [12]. A number of drugs have been shown to alter the natural history of ureteral calculi and to increase the likelihood of spontaneous passage, constituting so-called medical expulsive therapy (MET) [14].

Although MET has been shown to be efficacious in promoting stone passage, it is also associated with the additional cost of medication, even in those patients who are initially observed but ultimately require surgical intervention for their stones. Bensalah *et al.* performed a cost-effectiveness analysis to determine if MET was a cost-effective practice in patients with ureteral calculi [15]. They constructed a decision tree that compared the cost of each of two pathways of initial observation or surgical therapy. For each pathway, there is a potential for successful stone passage/treatment or for treatment failure thereby necessitating further intervention. Each of these pathways is associated with specific costs: the cost of medication, emergency room and office visits, hospitalization, radiographic imaging, surgery, and lost wages for time off work. Because patients who fail the primary treatment will additionally incur the cost of secondary treatment, the overall cost of a given treatment strategy is substantially impacted by the success rate of the primary treatment and is influenced by factors such as stone size and stone location. For example, observation alone is highly likely to be successful in a patient with a 2-mm distal ureteral calculus and therefore the additional cost of salvage URS is unlikely to be incurred.

For the model, they used data from the American Urological Association (AUA) Ureteral Stone Clinical Guidelines Panel, in which a meta-analysis of randomized MET trials showed that alpha-blockers provided a 29% absolute increase in rate of stone passage compared to placebo or no treatment [16]. Taking into account the success rates of MET from the meta-analysis and the success rates of spontaneous stone passage with observation alone from natural history studies and the control arms of MET RCTs, Bensalah *et al.* calculated a US$1132 cost advantage of MET over initial observation (US$1493 for MET vs US$2625 for observation alone) for the treatment of distal ureteral stones [15]. Indeed, because of the high cost of URS in the USA, MET was shown to be economically favorable even if MET was associated with only a 1% improvement in stone passage rates over observation alone. Since the cost of URS varies greatly among countries and healthcare systems but is uniformly quite high in the USA, the authors also concluded that MET was associated with cost savings over observation in several other countries as well.

Another American study by Brede *et al.* examined charges incurred by patients seen in the emergency department (ED) for acute ureteral stone events and evaluated the impact of MET over observation alone [17]. They took into consideration fees resulting from hospitalization, repeat visits to the ED, and surgery (all deemed "adverse events"), and found that use of MET decreased the rate of occurrence of adverse events by 24%, translating into a 29% decrease in cost compared to observation alone. Thus, MET, with its lower cost and substantial improvement in stone passage rates, is a cost-effective treatment strategy in patients with distal ureteral calculi of less than 1 cm in diameter, the group most thoroughly studied in RCTs. Whether this recommendation will hold true for patients with stones in other ureteral locations awaits further study. In patients without absolute indications for surgery it appears likely that short-term use of medication will be cost-effective even if it is only associated with a slight benefit in terms of efficacy because of the high cost of surgery.

Surgical intervention

Most ureteral calculi will pass spontaneously [16, 18]. However, for those stones that fail or are unlikely to pass based on size, location, or ureteral or patient anatomy, surgical intervention must be considered. The mainstays of treatment for ureteral stones are SWL and URS. The 2007 AUA Ureteral Stones Clinical Guidelines Panel stated that both SWL and URS are acceptable first-line treatment options for ureteral stones, but noted that URS was associated with a higher stone-free rate after a single procedure [16]. However, SWL and URS do differ with regard to cost for a variety of reasons, including differences in stone-free rates, complication rates, and cost of equipment. Furthermore, other factors besides cost influence the choice of surgical treatment, including stone characteristics, surgeon skill, and patient preference. Additionally, due to wide variations in cost parameters internationally, it is difficult to generalize conclusions drawn from one country to another.

Grasso *et al.* evaluated outcomes and cost in 112 patients treated with SWL or URS for ureteral stones, without stratifying patients according to stone location [19]. They found that while the cost of the initial treatment was comparable between the two modalities, the overall cost of SWL was substantially higher than the cost of URS because a greater number of patients in the SWL group required a secondary or auxiliary procedure (31% vs 3%, respectively). Parker *et al.* also found a cost advantage of US$1932 for URS over SWL for the initial treatment of patients with proximal ureteral stones [20]. The cost difference became even more pronounced (US$6205) when taking into consideration the cost of additional procedures, imaging, and office visits.

Several studies have examined the cost of treating particular subgroups of patients with ureteral calculi. Salem conducted a prospective, randomized trial of SWL versus URS for proximal ureteral calculi in Egypt, and compared the overall cost of treatment, including the cost of preoperative evaluation, surgery, secondary and auxiliary procedures, and emergency room and clinic visits [21]. Although URS as a procedure was more costly than SWL [3000 vs 2500 Egyptian pounds (EP)], overall cost favored URS (5700 EP for URS vs 6500 EP for SWL), because 35% of SWL patients required emergency room visits for renal colic at a mean cost of 1150 EP per patient. Wu *et al.* also compared the cost of treating patients in China with large (>1 cm) proximal ureteral calculi with URS or SWL and found that URS was less costly (US$953) than SWL (US$1401) [22].

One factor that seems to universally impact the cost of the procedure is the need for hospitalization. Although in the USA both URS and SWL are performed largely on an outpatient basis, in many other countries URS requires a hospital stay. A Dutch study by Bierkens *et al.* comparing SWL and URS for the treatment of middle and distal ureteral calculi found SWL to be less costly due to a substantially longer hospital stay for the URS patients, averaging 3 days [23]. Indeed, Anderson *et al.* found that URS was slightly less costly than SWL in their US hospital, but only if URS patients were treated as outpatients [24]. In a study of patients with distal ureteral stones in which all patients were hospitalized for at least one night, Kapoor *et al.* determined that URS cost 60% less than SWL, primarily due to the higher initial success rate [25].

Table 66.1 summarizes studies comparing the cost of URS and SWL for ureteral calculi. However, it is difficult to directly compare the various studies as there is no consensus in the literature regarding the specific factors that should be included in cost calculations and from whose perspective cost is determined. For example, all of the studies listed in Table 66.1 used charge, rather than cost data, and the charges comprising the total varied among studies. While all studies included charges for the primary surgical procedure, Bierkens *et al.* tallied only the surgeon/anesthesia fees, choosing not to include the cost of equipment/disposables [23]. Other studies included the cost of preoperative evaluation [21, 22, 25], while some presumed that these costs would be similar in both groups and therefore excluded them from analysis. Only two studies specifically evaluated and included the charges associated with complications, including emergency room care as well as unplanned hospital admissions or nephrostomy tube/ureteral stent placements related to obstruction [21, 25]. Finally, Bierkens *et al.* additionally

Table 66.1 Cost studies comparing ureteroscopy (URS) versus shock-wave lithotripsy (SWL) for the management of ureteral stones.

[a]Stone-free rate from initial procedure only, performed one time except in Bierkens *et al.*, where only stone-free rates after all primary procedures (either URS or SWL) were performed were reported.
[b]Does not include stent removal procedures.
[c]Definition of "overall cost" varied between papers in what was included but is based on charge data in all cases. See text for details.
[d]Two groups were treated with SWL: one using the Dornier HM3 (n = 27) and one using the Siemens Lithostar (n = 22).
2° Tx, secondary treatments, all surgeries performed after single procedure of primary treatment, including retreatments/salvage treatments with either SWL or URS as well as salvage open or PCNL procedures.

factored in a "disability cost," estimated at US$60/day, in an attempt to account for differences in lost work productivity related to surgical treatment of a ureteral stone. This cost was accrued for each day spent in the hospital, undergoing a procedure, or attending an office visit [23].

To account for differences in cost and success rates for the two procedures from institution to institution, decision analysis models provide theoretical tools that, through a series of assumptions about treatment choices, outcomes, and cost, can be used to compare the cost of different treatments. Wolf *et al.* developed a model comparing SWL and URS for the treatment of distal ureteral calculi in which they assumed success rates of 92% for URS and 74% for SWL based on available literature [26]. By their calculation, the cost of SWL would have to drop by US$1107 to be equivalent with URS. Lotan *et al.* used a decision-tree analysis (Figure 66.1) to compare observation, SWL, and URS for the treatment of patients with ureteral stones, and additionally stratified patients according to stone location (proximal, middle, or distal ureter). For each stone location, they determined that observation was the least costly approach, provided the cost of missed work and additional treatment or evaluation (such as emergency room visits) did not exceed US$456 [27]. Comparing the two surgical treatment modalities, URS was less costly than SWL for all ureteral locations by US$1440, US$1670, or US$1750 for patients with proximal, middle, and distal ureteral stones, respectively, primarily due to the high cost of purchasing and maintaining a lithotripter, which was factored into the analysis. Two-way sensitivity analyses were performed for URS and SWL at different success rates and costs to determine the overall cost of treatment based on the model (Table 66.2). This analysis allowed the creation of a universal table by which the least costly treatment modality within a large range of success rates (50–95%) and costs (US$2000–5000) can be identified, thereby making the table generalizable to any hospital or country.

As long as lithotripters cost more than ureteroscopes, the lack of greater efficacy of SWL makes URS the more cost-effective in managing ureteral and most renal stones (see below). Even the fragility of ureteroscopes, with added repair costs, is balanced by the high annual maintenance costs of the lithotripter.

Renal calculi

The cost of treating renal calculi has not been scrutinized as thoroughly as that for ureteral calculi. However, the cost of treating particular subgroups of patients with renal calculi, such as staghorn and lower pole calyceal calculi, has been addressed. In general, the most commonly used treatment modalities for renal calculi are URS, SWL, and percutaneous nephrolithotomy (PCNL).

Staghorn calculi

The AUA Clinical Guidelines Panel on Staghorn Calculi recently updated their 1994 Guidelines [28] and recommended PCNL monotherapy as the optimal treatment modality for staghorn calculi [29]. The panel emphasized the liberal use of flexible nephroscopy to achieve a stone-free state after initial PCNL, which is a departure from the 1994 Panel recommendation of combination therapy (PCNL/SWL) as first-line treatment. However, there are a few limited clinical circumstances where SWL monotherapy may be acceptable for the treatment of staghorn calculi, such as a small volume stone in a nondilated collecting system [30]. However, despite few clinical indications, SWL monotherapy continues to be used by some practitioners for the management of unselected patients with staghorn stones.

Chandhoke used a model to determine the "cost-effectiveness index" for different treatments for staghorn calculi (i.e. the average cost of rendering one patient stone free), defined as the treatment cost divided by the stone-free rate, plus cost of complications multiplied by the complication rate [31]. Using *charge* data from his own institution and efficacy and complication rates from the 1994 AUA Staghorn Calculi Guidelines, he formulated a decision analysis evaluating SWL, PCNL, and combination therapy (PCNL/SWL). He calculated that SWL monotherapy was the least cost-effective modality followed by combination therapy, with PCNL monotherapy the most cost-effective, although the actual cost-effectiveness index varied according to the type of secondary treatment utilized (percutaneous-based vs URS). Assuming URS as the secondary procedure, cost-effectiveness indices were US$52 251 for SWL monotherapy, US$48 095 for combination therapy, and US$36 672 for PCNL monotherapy. He further stratified patients by stone volume, according to the classification scheme used by Lam *et al* [30], to compare the cost-effectiveness of SWL monotherapy and combination therapy, and found that the two modalities were cost-equivalent when the stone burden was less than 500 mm^2 but that combination therapy was more cost-effective for stones larger than 500 mm^2.

Based on these studies, PCNL monotherapy is the preferred initial modality for the management of staghorn calculi, based on superior efficacy, efficiency, and cost-effectiveness.

Nonstaghorn renal calculi

For nonstaghorn renal calculi, SWL has long been the treatment of choice, due to high stone-free rates and low

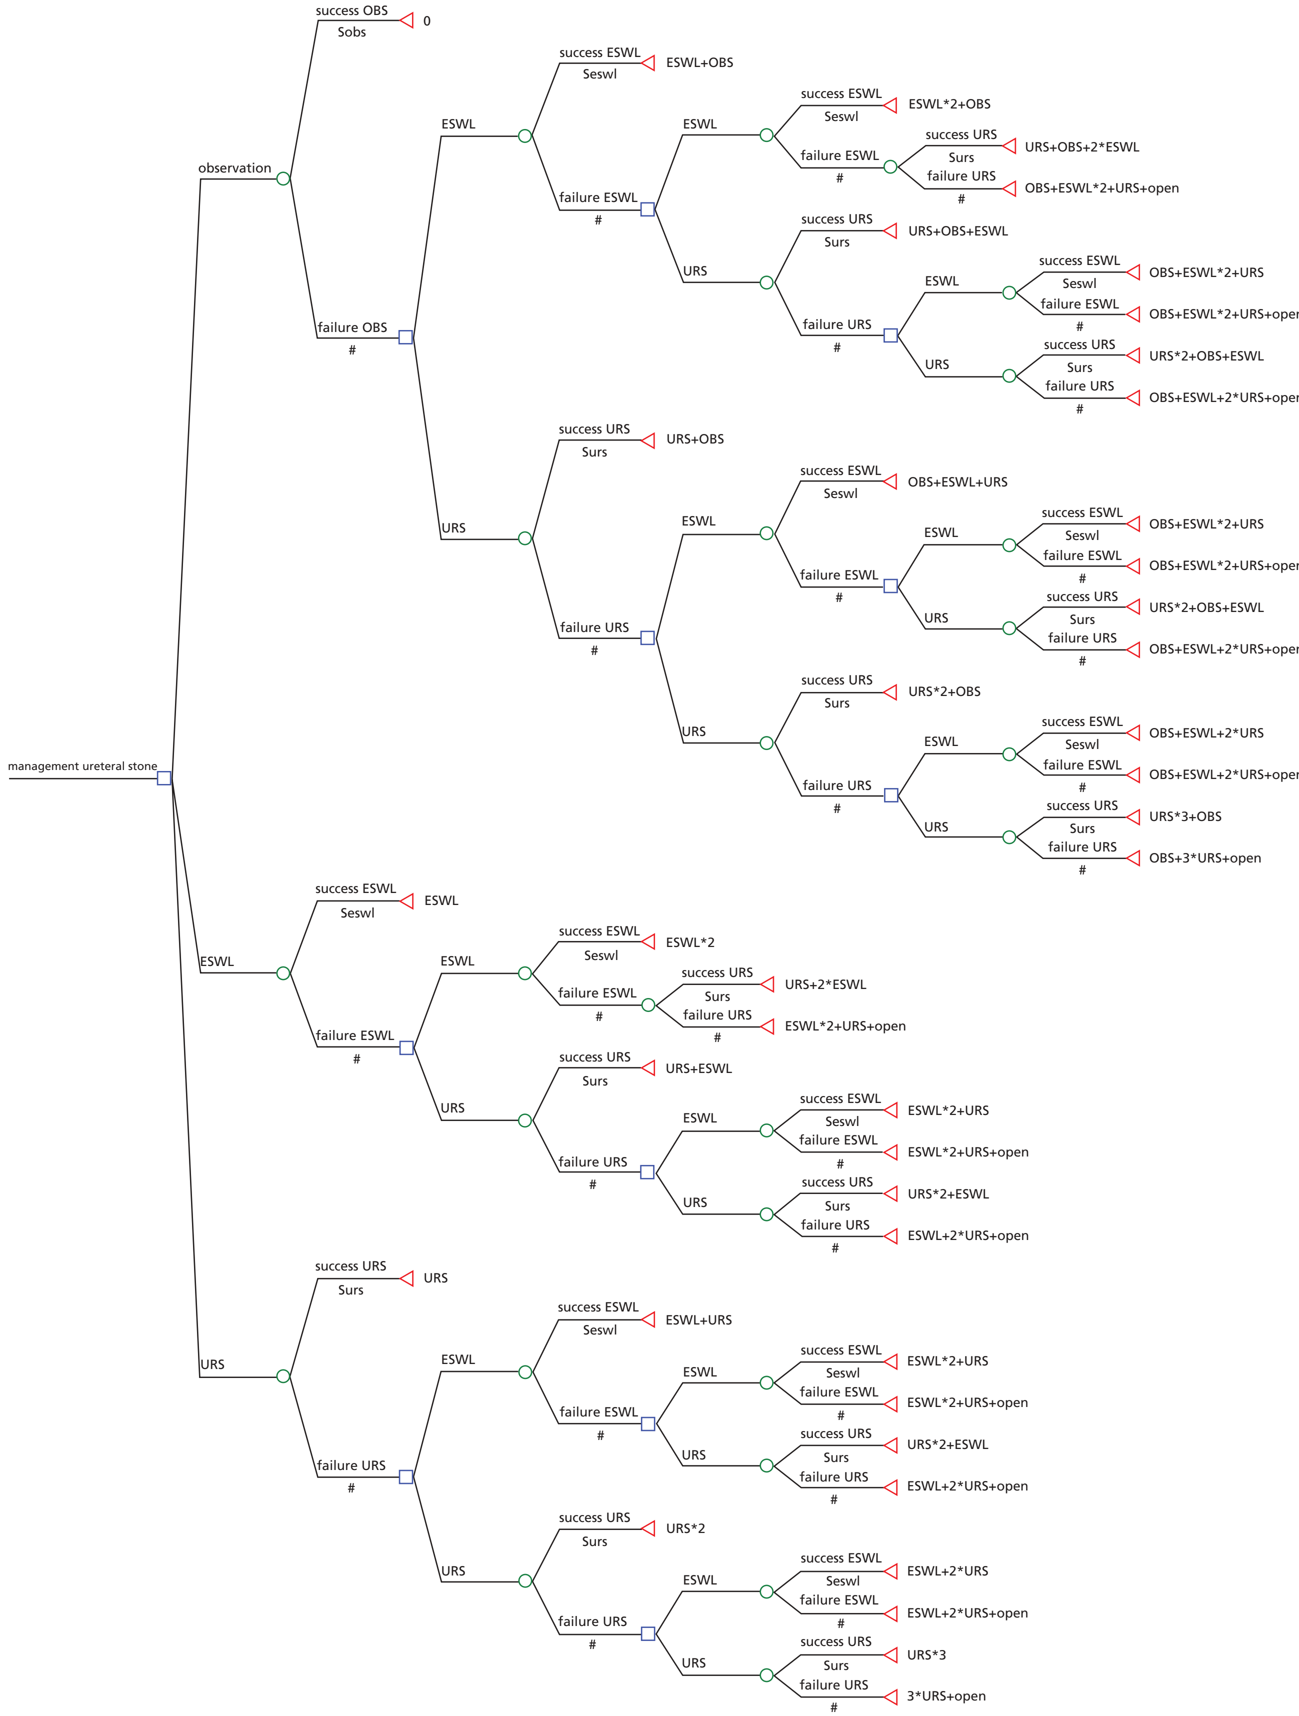

Figure 66.1 Decision-tree model of three initial treatment options for ureteral calculi, including ureteroscopy (URS), extracorporeal shock-wave lithotripsy (ESWL), and observation (OBS), and secondary, tertiary, and quaternary treatment options after failure. For each initial treatment strategy, there are possible outcomes, each of which can lead to further outcomes. Each alternative outcome has cost consequences, such that the total cost of an initial treatment strategy is the sum of the costs of each individual outcome along the pathway. Seswl, success of SWL; Sobs, success of observation; Surs, success of URS; Open, open salvage procedure (reproduced from Lotan *et al.* [27], with permission from Elsevier).

morbidity. Indeed, SWL remains the only noninvasive surgical treatment for renal and ureteral calculi. However, it is known that SWL stone-free rates are inversely proportional to stone size, and that retreatment and complications rates vary directly with stone size. Consequently, alternative treatments such as PCNL and URS have been considered for the treatment of large renal calculi. No analyses have evaluated the cost-effectiveness of various treatment modalities for the management of small-to-moderate renal calculi, likely because it is easy to justify SWL on the basis of its noninvasiveness and effectiveness for stones of this size. However, Hyams and Shah compared the cost-effectiveness of URS versus PCNL for the management of patients with large (2–3 cm) stones in a retrospective review of 39 patients [32]. Taking into account the number of primary procedures (intended treatment modality) as well as the need for secondary procedures (to further achieve a stone-free state), they calculated the cost difference between the two modalities using Medicare reimbursement rates. They concluded that, despite a substantially lower stone-free rate with URS compared with PCNL (47% vs 89%, respectively, $P = .01$), URS was ultimately less costly than PCNL (US$6,675 vs US$19 845, respectively, $P = .0001$). The cost difference between the two treatment modalities was due in part to the difference in the need for repeat procedures, which were required in 55% of the PCNL group (11 of 20) but only 5% of the URS group (1 of 19). Of note, however, the URS patients had a higher residual stone rate, suggesting that the authors were less likely to perform second-look URS than second-look PCNL. Also of importance, stone-free status in this series was evaluated with kidneys, ureters, and bladder (KUB) scan (before 2007) or CT (after 2007) for PCNL patients, while URS patients were evaluated with renal ultrasound with or without KUB, further limiting the validity of comparison, and artificially favoring URS.

This analysis highlights the difference between a *cost comparison*, which identifies the less costly procedure, versus a *cost-effectiveness analysis*, which takes into account not only cost but also efficacy. For example, if procedure A costs US$1000 and is 100% effective and procedure B costs US$500 but is only 25% effective, then procedure B would be less costly in a cost comparison study but would fare less well in a cost-effectiveness study. It is also important to distinguish *cost* and *compensation*, which unfortunately are frequently disparate in medicine. Some procedures yield high profit margins while others are loss leaders. As such, the use of reimbursement rates as a measure of "cost" is inappropriate, since they reflect not the sum of the resources utilized by the hospital, but rather the amount the hospital will collect for a procedure. Medicare reimbursement schedules are an artificially set rate of compensation that is not necessarily linked to the actual cost of materials and personnel for hospitals. Furthermore, the ratio between the actual cost of a procedure and the reimbursement from Medicare is not fixed, which can thereby create inaccuracies when using this type of data to compare different procedures.

Lower pole calyceal calculi

Another area of controversy in the treatment of renal calculi is the optimal management of lower pole renal calculi. Albala *et al.*, representing the Lower Pole Stone Study Group, reported the results of a prospective, randomized clinical trial comparing SWL and PCNL for the management of isolated lower pole stones [33]. They found superior overall stone-free rates for PCNL versus SWL (95% vs 37%, respectively), with more pronounced differences between the two modalities evident with increasing stone size. May and Chandhoke conducted a cost analysis similar to Chandhoke *et al.*'s analysis of staghorn calculi (see above), using charge date from their own institution, and published success and complication rates. According to their analysis, despite lower initial success rates, SWL was more cost-effective than PCNL for the management of patients with lower pole stones of less than 2 cm, while PCNL was more cost-effective for patients with stones greater than 2 cm [34].

Further analyses of treatment modalities for lower pole calyceal stones were conducted by the Lower Pole Stone Study Group, which subsequently incorporated URS into its treatment algorithm. In an RCT comparing SWL and URS for the treatment of patients with lower pole stones of 1 cm or less, it found that stone-free rates were not statistically significantly different between the two treatment modalities (35% vs 50%), although secondary parameters tended to favor SWL [35]. For lower pole stones between 1 and 2.5 cm, patients were randomized to URS or PCNL since SWL outcomes had previously been shown to be unacceptable for stones in this size range. In this group of 42 patients, PCNL stone-free rates were higher than URS (71% vs 37%, $P < .05$), and although hospital length of stay was shorter for URS than PCNL, overall convalescence time was no different between the two groups [36]. Unfortunately, there are no published cost-effectiveness analyses based on these RCTs.

Cost factors for percutaneous nephrolithotomy

PCNL has become the treatment of choice for large and/or complex renal calculi based on high stone-free rates and acceptable morbidity. However, there are patient factors and procedural choices in the percutaneous management of renal calculi that impact the overall cost

of the procedure. In order to perform the procedure in a cost-effective manner, it is critical to understand the factors that most prominently impact cost so as to target those areas for possible cost-reducing modifications. Bagrodia *et al.* retrospectively reviewed hospital cost (not charge) information from their hospital billing department for 179 patients who underwent PCNL, and then performed univariate and multivariate analyses to determine the most important predictors contributing to cost [37]. On univariate analysis, preoperative urinary infection, use of allopurinol, and stone size were associated with higher cost; however, only stone size proved to be an independent predictor of higher cost on multivariate analyses. On further analysis, the impact of stone size seemed to be primarily related to the increased need for second-look flexible nephroscopy procedures in patients with larger stone burdens. Of note, factors that did not predict cost were patient age, comorbidities, and obesity.

A number of investigators have shown that bilateral simultaneous PCNL can be performed safely and effectively [38–40]. Bagrodia *et al.* compared the cost-effectiveness of simultaneous bilateral PCNL (SB-PCNL) with staged bilateral PCNL [41]. In this study, the authors used actual cost information obtained from their hospital billing department for patients undergoing SB-PCNL and for patients undergoing unilateral PCNL with current procedural terminology (CPT) codes that were matched to a group of actual patients undergoing SB-PCNL. The authors chose to create a theoretical cost for staged bilateral PCNL based on comparable CPT codes matched with the SB-PCNL group so as to prevent a selection bias against the patients treated in a staged fashion, which in their practice typically included only those with very large bilateral staghorn calculi. SB-PCNL was associated with a cost saving of US$4374–5126 compared to staged PCNL, depending on the combination of CPT codes used for the two sides (50080 for <2-cm stones, 50081 for >2-cm stones). Cost savings in the SB-PCNL procedures were attributed to a variety of factors, including decreased overall operating room equipment costs (i.e. much of the same equipment could be reused for the second renal unit during SB-PCNL), shorter overall operating room time, and fewer imaging studies since both sides could be imaged simultaneously in the SB-PCNL group. In addition, they also found that SB-PCNL procedures were not associated with a longer hospital stay than unilateral PCNL, thus generating significant cost savings for the hospital and insurer. It is noteworthy that differences in surgeon fees between staged and simultaneous bilateral PCNL, however, favor staged bilateral PCNL, which may discourage practitioners from performing an overall less costly procedure (SB-PCNL) that is beneficial to patients.

In an attempt to decrease the morbidity of PCNL, some investigators have advocated the use of the so-called "mini-perc" procedure, whereby a smaller nephrostomy tract is created in the hope of reducing blood loss, renal damage, and postoperative pain [42, 43]. Although this procedure has not been widely accepted because the advantages have proven to be more theoretical than real [44], Feng *et al.* compared the cost of mini-perc using a 26F working sheath with standard PCNL using a 34F sheath [45]. Using hospital billing data, they determined that the cost of mini-perc was equivalent to that of standard PCNL. However, "tubeless" PCNL, in which an internal double pigtail ureteral stent is left in place *in lieu* of a nephrostomy tube to drain the kidney postoperatively, proved to be less costly than either standard PCNL or mini-perc (US$5562 for tubeless PCNL compared with US$7555 for standard PCNL and US$6565 for mini-perc). Of note, however, since this was a nonrandomized study, selection bias likely contributed to the choice of "tubeless", mini-perc, and standard PCNL, which could impact outcomes and cost.

One of the most important determinants of the overall cost of PCNL is the need for second-look flexible nephroscopy to remove residual fragments. While the goal of any surgical stone procedure is to completely remove all stone material, in practical terms this is achievable to a greater or lesser degree depending on the procedure. With the introduction of SWL, the concept of "stone free" became relative, and leaving behind small residual fragments was considered acceptable because of the noninvasive nature of the procedure. Because PCNL provides for manual retrieval of all stone fragments through a hole in the kidney, residual fragments are more readily addressed and leaving them behind is considered less acceptable.

A number of investigators evaluating the fate of residual fragments after SWL [46–50] and PCNL [51] have concluded that even small (<4 mm) residual fragments place patients at risk for future stone events. Although the cost of treating versus observing residual fragments after SWL has not been addressed, Raman *et al.* created a decision-tree model to evaluate the cost-effectiveness of second-look flexible nephroscopy for residual stones after PCNL [52]. Using Kaplan–Meir estimates to determine the likelihood of occurrence of a stone-related event, these authors previously determined that patients with fragments of greater than 2 mm in size had estimated 3- and 5-year survival rates (where survival indicates freedom from a stone-related event) of 56% and 33%, respectively, compared with 87% and 65%, respectively, for patients with residual fragments of 2 mm or smaller ($P = .04$) [51]. They constructed an algorithm to indicate the possible pathways a patient with residual stones could follow, along with the likelihood of each

Table 66.3 Two-way sensitivity analysis evaluating cost-effectiveness for second-look flexible nephroscopy for residual fragments (RFs) after percutaneous nephrolithotomy. Shaded areas indicate permutations where incurred RF costs are within US$100 of or greater than US$2475 fixed cost of second-look flexible nephroscopy (reproduced from Raman *et al*. [52], with permission from Elsevier).

Likelihood of symptomatic stone event (%)

event. For the model, they used data from the literature on the natural history of residual fragments after SWL and PCNL in combination with cost data from their own institution regarding hospitalization, medications, lost wages, emergency room visits, and secondary surgeries/procedures. They determined that for residual fragments of 4 mm or smaller, a strategy of observation over second-look flexible nephroscopy was more cost-effective; on the other hand, for patients with residual fragments larger than 4 mm, second-look flexible nephroscopy was a cost-effective approach. Two-way sensitivity analysis, by which the likelihood of successful conservative management of residual fragments and the likelihood of a symptomatic stone event are varied over a range of possibilities, is shown in Table 66.3, which allows the cost-effectiveness of second-look flexible nephroscopy for a given set of outcome parameters to be determined.

Combining information from the natural history of residual stones after PCNL and cost data from the cost-effectiveness model, it appears that observation is a reasonable strategy in patients with residual fragments after PCNL of 2 mm or smaller, and second-look flexible nephroscopy is indicated in patients with residual fragments larger than 4 mm. For patients with residual fragments of 2–4 mm, if observation is considered, it is at the expense of a higher likelihood of experiencing a stone-related event.

There is a distinct need for more prospective studies evaluating the cost-effectiveness of URS, SWL, and PCNL for the treatment of renal calculi. While SWL is noninvasive and associated with low morbidity, the higher likelihood of secondary procedures adds an additional incremental cost compared to some other more efficacious modalities. Likewise, while improvements in ureteroscope design and the use of ureteral access sheaths has expanded the indications for URS and increased its use for large-volume renal stones, the ability to manage larger stone burdens ureteroscopically comes with the added cost of longer operative times. Finally, PCNL is the most efficacious procedure with regard to stone-free rates, but the associated hospital stay and higher complication rate make this modality costly, albeit in many circumstances cost-effective. Future studies need to take into account both stone location and stone size for determining the most cost-effective approach among these treatment modalities for the management of patients with renal calculi.

Medical evaluation and management

Given the high rate of recurrence of nephrolithiasis, a medical prophylactic program to reduce the likelihood of recurrent stones seems desirable. Indeed, a variety of medical treatments has been shown to decrease stone recurrence compared to no treatment [53]. However, drug treatments can be costly and may be associated with side effects that themselves reduce quality of life. Dietary measures alone have also shown effectiveness in reducing stone recurrence without additional cost,

but to a lesser extent than drug therapy and at the expense of lifestyle changes. Furthermore, not every recurrent stone becomes symptomatic or requires treatment. Therefore, the benefit of preventing recurrent stones with medication or dietary modification must be weighed against the cost of treatment and the risk of side effects or the inconvenience of making a lifestyle change. Because of these conflicting outcomes, several authors have attempted to investigate the economic consequences of these varied approaches.

Parks and Coe compared rates of stone occurrence before and after the initiation of medical therapy, and calculated the cost savings of metabolic evaluation and medical treatment [54]. Upon entry into their stone clinic, patients were extensively evaluated with blood and urine studies and then counseled on dietary measures aimed at minimizing urinary stone risk factors. Additionally, select patients were prescribed medications such as thiazides, allopurinol, and potassium citrate, according to their metabolic background. With this diagnostic and treatment approach, the authors reported a stone remission rate of 83%. By applying this remission rate, along with estimates regarding the cost of surgical procedures, rates of stone passage events, and need for hospitalization, they estimated that their medical prophylactic regimen resulted in cost savings averaging US$1162–3162/patient/year. Of note, however, there was no true control group in this study, and pretreatment stone occurrence rates were based on patient recall, which is subject to bias. Furthermore, the "control" group did not systematically incorporate dietary measures, which have been shown to reduce recurrence rates [55–57], until after entry into the stone clinic. Therefore, the effectiveness and cost savings attributed to medical therapy in this study are likely overestimated.

Because patients differ in the aggressiveness of their stone disease, it is likely that the initiation of medical therapy may be efficacious and cost-effective in some, while dietary management alone may be sufficient in less aggressive or first-time stone formers without significant risk factors. Chandhoke used a cost model to determine the stone recurrence rate at which medical therapy becomes cost-effective [5]. For the model, he assumed that all recurrent stones became symptomatic and required either an emergency room visit or surgery. Additionally, he assumed a limited metabolic evaluation consisting of an office visit, two 24-h urine collections, imaging studies at 6-month intervals, and drug therapy distributed according to a published study. According to the model, at a recurrence rate of 0.3–4.0 stones/year, the cost of medical evaluation and treatment becomes equivalent to the cost of conservative therapy.

This type of more advanced analysis allows stratification of patients according to the aggressiveness of their disease, but was limited in that it evaluated only one strategy of metabolic evaluation and treatment and it likely overestimated the probability that a recurrent stone will become symptomatic or require treatment, thereby increasing the cost of conservative therapy.

Lotan *et al*. performed a more comprehensive cost-effectiveness analysis using a decision-tree model to compare the costs of six medical treatment strategies: dietary measures alone (conservative), empiric drug treatment (empiric), or directed drug therapy based on simple (SMEM) or comprehensive (CMEM) metabolic evaluation with either all patients receiving drug therapy (SMEM or CMEM) or only those patients with demonstrable metabolic abnormalities receiving drugs (modified SMEM and modified CMEM) [58]. The model took into account accrual of cost for evaluation, medications, emergency treatment, and surgical management for recurrent stones.

For first-time stone formers, conservative therapy was the most cost-effective strategy, resulting in a stone recurrence rate of one episode every 14 years (Table 66.4). For recurrent stone formers, conservative therapy was still the least costly approach, but it was associated with an unacceptably high recurrence rate of 0.3 stones/patient/year. The four drug treatment strategies were all more costly than conservative treatment (US$885–1187/year vs US$258/year for the conservative approach), but drug therapy further reduced recurrence rates by 60–86% over dietary therapy. A strategy of modified medical evaluation and management by which all patients received drug therapy after a limited evaluation (modified SMEM) was marginally more effective than empiric therapy and slightly more costly. Comprehensive evaluation and targeted medical therapy had equivalent or greater cost with little or no improvement in efficacy over empiric or modified SMEM.

Treatment strategies in which all patients received medication, regardless of 24-h urine findings, significantly improved recurrence rates (by up to 60%) over strategies where only patients with a metabolic abnormality were prescribed drugs. Furthermore, since comprehensive medical evaluation and management significantly increased the cost of treatment without added efficacy, either empiric therapy or a modified SMEM in which all patients received drug therapy was recommended. Interestingly, since conservative therapy (the least costly approach) was associated with an unacceptably high recurrence rate, this model demonstrated the practical cost-effectiveness of treating *all* recurrent stone formers with medication despite the relatively high cost of drugs, due to the associated significant reduction in recurrence rates. Now that potassium citrate is available in generic form, the cost-effectiveness threshold for medical therapy should be further lowered.

Table 66.4 Cost of medical therapy model summary and treatment outcomes (modified from Lotan *et al.* [58], with permission from Elsevier).

		Medical treatment			First-time stone formers		Recurrent stone formers	
Strategy	Evaluation	For hypercalciuria (% of patients)	For other metabolic causes (% of patients)	For no metabolic abnormality (% of patients)	Stone formation rate (stones/patient/year)	Model cost (US$/year)	Stone formation rate (stones/patient/year)	Model cost (US$/year)
Conservative	None	No drug	No drug	No drug	0.070	133	0.300	258
Empiric	None	K-Cit	K-Cit	K-Cit	0.013	966	0.057	990
Modified SMEM	Simplified	Tz + K-Cit (35)	K-Cit (35)	K-Cit (30)	0.011	1085	0.048	1104
SMEM	Simplified	Tz + K-Cit (35)	K-Cit (35)	No drug	0.028	835	0.120	885

SMEM, simplified metabolic evaluation and management; CMEM, complete metabolic evaluation and management; Tz, thiazide; K-Cit, potassium citrate.

The advantage of this decision-tree model is that the cost-effectiveness of any medication can be determined by inputting its associated risk reduction and cost, and evaluating it using any of the six metabolic evaluation and treatment strategies.

Because of differences in healthcare systems, there is significant disparity in the cost of stone management worldwide. As such, comparison of treatment costs from one country to the next may not be meaningful [5]. Lotan *et al.* utilized a decision-tree model to evaluate the cost-effectiveness of medical evaluation and treatment strategies in a variety of healthcare systems [4]. Using data derived from a published international cost survey [5] and limiting the treatment arms to conservative therapy, empiric treatment, and comprehensive metabolic evaluation with targeted medical therapy in those found to have a metabolic abnormality, they used the model to determine the most cost-effective strategy in countries for which they had cost data. Conservative therapy based on dietary therapy alone was the most cost-effective strategy in first-time stone formers in all 10 countries. For recurrent stone formers, the most cost-effective strategy in all countries except the UK was conservative therapy, followed by empiric therapy and then directed medical therapy. In the UK, where the low cost of drug therapy is estimated at only US$29/patient/year, empiric therapy was the least costly strategy. Likewise, in other countries with relatively low medication costs, like Turkey and Switzerland, the cost difference between conservative and empiric therapy was marginal, although empiric therapy was associated with a significant improvement in efficacy. According to two-way sensitivity analysis, more than one stone episode/year would be required to render empiric therapy cost superior to conservative treatment in all analyzed countries except the UK and Switzerland. In countries like the USA where drugs costs are high, conservative therapy offered an even greater cost advantage. In their model, since there was little difference in efficacy between targeted and empiric medical therapy, the use of metabolic evaluation to direct medical therapy did not prove to be cost-effective in any of the countries studied.

Several European studies have concluded that medical therapy is cost-effective in their respective countries. Using medication costs of 220 Euros/year and a cost/stone episode of 2500 Euros in Sweden, Tiselius calculated that with an initial stone recurrence rate of 0.3 stones/patient/year, a medication that reduced stone recurrence rates by 50% would result in a cost savings of 375 Euros/patient/year [59]. Strohmaier and Hörmann, presuming a higher recurrence rate of 50% per year, found that a 40% risk reduction associated with medical therapy would result in yearly savings of 333.1 million DM for the German healthcare system [60].

It is clear from these international cost analyses that differences in the cost of medication and surgery across healthcare systems, largely based on subsidization, are responsible for differences in the cost-effectiveness of medical management treatment strategies. When medication costs are regulated or subsidized, the low cost of

medication favors drug therapy. On the other hand, when the cost of medications is high, the relatively infrequent need for surgery to treat stone recurrences and the fixed reimbursement for surgical procedures favor a conservative approach.

Conclusions

Careful cost analyses are the key to developing cost-effective treatment strategies. However, cost analyses are only as accurate as the cost data used to derive them and they are only useful in the context of efficacy and efficiency. Consequently, cost-effectiveness models, which take into account not only cost but also efficacy, are invaluable for comparing different treatment strategies and for comparing treatments in different institutions or healthcare systems. However, even cost-effectiveness models are only as valuable as the assumptions and cost data inputted into them and must be carefully scrutinized. Their advantage over cost analyses is that they can be applied to any institution or country by changing the variables, such as success rates or cost. While determination of cost-effective practices is invaluable at a societal level, we must not lose sight of the impact of treatment decisions on the individual. The experience of passing a stone in an individual patient cannot be accurately or fairly described in dollars alone; nor is cost the only factor that should be considered when determining optimal treatment strategy. Thus in many situations, a treatment decision is chosen to maximize efficacy or another outcome (such as stone recurrence rate) despite its higher cost.

CHAPTER 67

Long-Term Stenting of the Ureter

Evangelos Liatsikos,[1] Panagiotis Kallidonis,[1] Dimitrios Karnabatidis[2] & Theodoros Petsas[2]

[1]Department of Urology, University of Patras, Patras, Greece

[2]Department of Radiology, University of Patras, Patras, Greece

Introduction

Ureteral stents are widely used in urologic clinical practice. The efficacy of ureteral stents in the management of various urologic conditions causing upper urinary tract obstruction has been extensively proven and their contribution to urology remains enormous.

Ureteral stents are available in various shapes and made of various materials. Ureteral stents can be divided into polymeric (PSs) and metal mesh stents (MSs). PSs are usually composed of polyurethane and silicon-based polymeric biomaterial. A unique category of PSs is the biodegradable stents which are composed of biomaterials such as poly-L-lactide-co-glycolide (PLGA) or L-lactide-glycolic acid copolymer. MSs are based on metal alloys such as MP35N, nickel–cobalt or stainless steel. Stent designs depend on their use and composition. The most commonly used PS design is the double-pigtail (double-J) design, which is characterized by coil-shaped stent ends. MSs are either MSs identical to those used in coronary vessels or double-J stents composed of metal wire (Resonance) [1].

Regardless of the stent design and composition, the use of ureteral stents is associated with several complications, which limit their use and necessitates the escalation of research towards the introduction of the "ideal" ureteral stent. The properties of the ideal stent include the ability to hold its position (memory) over time (durometry), easy manipulation of its shape (elasticity), and excellent tensile strength while having elongation capacity. Moreover, placement of the ideal ureteral stent should not be associated with degradation of its structure and function (biodurability) or influence the urothelium (biocompatibility). The ideal stent should be radio-opaque and therefore visualized by fluoroscopy [1, 2]. Patient comfort and resistance to bacterial colonization could also be considered important properties of the ideal stent. The ideal stent is currently not available and the problems related to ureteral stenting remain an issue, especially in cases requiring long-term stenting to maintain ureteral patency.

Indications for ureteral stents

The insertion of stents in the ureter serves several purposes: relief of ureteral obstruction, promotion of ureteral healing, and prevention of possible complications. Postoperative nephrostomies are usually avoided by the use of ureteral stents. The stent acts as a scaffold for the growth of epithelium, promotes ureteral healing by aligning the ureteric wall and reduces extravasation around the ureter (less inflammation) [3, 4].

The use of ureteral stents for the management of stone disease provides obstruction/hydronephrosis relief, and reduction of colic and infection incidents. Double-pigtail PSs are inserted in lithiasis patients for temporary management of stone-related obstruction [5]. An absolute indication for the management of stone cases by ureteral stenting is the concomitant presence of ureterolithiasis and active infection [6]. The routine use of double-pigtail PSs after shock-wave lithotripsy (SWL) and ureteroscopy (URS) remains questionable

Smith's Textbook of Endourology, Third Edition. Edited by Arthur D. Smith, Gopal H. Badlani, Glenn M. Preminger, Louis R. Kavoussi.

[7, 8]. Transplantation-related ureteral strictures are an indication for PS insertion [9–11]. Partial ureteral lacerations are successfully managed by double-pigtail stent placement [12] as are ureteropelvic junction obstructions (UPJO); it provides relief of flank pain and healing of the repaired site after pyeloplasty and endopyelotomy [5]. PSs are also inserted intraoperatively in reconstruction of the ureter to, as mentioned above, provide alignment of the area of the anastomosis and act as scaffold around the ureter, which may eventually facilitate the healing process. Moreover, the presence of a ureteral stent minimizes urine extravasation and reduces ureteral wall edema [5]. Ureteral stents make a significant contribution to the treatment of ureteral fistulas: 85% of such cases are efficiently healed with the use of a PS [13].

Malignant ureteral obstruction remains a challenging field for PSs. Despite the use of PSs as an alternative to nephrostomy tubes in the above cases, extrinsic malignant ureteral obstruction managed by PSs is associated with high failure rates [14, 15]. Two ipsilateral pigtail ureteral stents were proposed as a method to address cases of single stent failure, with various success rates. A new double-lumen double-pigtail stent has also been introduced and evaluated in a pig model, with promising results [6, 16].

MSs have been used for the management of extrinsic malignant ureteral obstruction in cases where PSs have failed. The reported success rates were high and the method proved to be useful [2]. The use of MSs has been expanded in benign cases of ureteroileal anastomotic strictures and UPJO, with promising success rates. In fact, long follow-up of the former indicates that MSs are an alternative to challenging reintervention procedures performed for ureteroileal anastomotic strictures and UPJO [2, 16–18].

Complications of ureteral stents

Long-term urinary drainage by ureteral stent insertion is limited by several complications. These complications are related to the design and material of the stent. Major problems of stent use include infection, patient discomfort, encrustation, migration, and hyperplastic reaction.

Stent syndrome

The "stent syndrome" represents the most common double-pigtail PS-related complication and is characterized by irritative voiding symptoms, flank pain, suprapubic discomfort, and occasional hematuria [5, 6]. Urinary system symptoms may be present in up to 80% of patients with stented ureters. Bladder pain (80%) and incontinence (60%) are important problems for these patients [19]. Insertion technique and stent characteristics are unrelated to these symptoms, while selection of the appropriate stent length is related to reduced morbidity [5, 20, 21]. Voiding symptoms, such as urgency and dysuria, attributed to irritation of the bladder floor by the stent, were significantly more frequent in patients with longer stents [5]. Nevertheless, flank pain was not reduced by the stent length as this symptom is related to vesicoureteric reflux [22]. Softer or tapered lumenless tails have been also proposed for symptoms reduction [23, 24].

Stent migration

Migration of the PSs is associated with stent design. Double-pigtail stents are less prone to migration in comparison to single-pigtail stents. PSs usually migrate towards the kidney rather than towards the bladder. The insertion of the stent under direct cystoscopic vision is advised and the formation of a full loop in the bladder should be confirmed. Migrated stents require URS management for their removal [25]. Challenging cases of ureteral stent extraction require ureteral orifice incision and the use of devices such as embolectomy catheters, and ureteral balloons and baskets [26]. Covered MSs have been associated with rates of migration up to 81.2% [27].

Encrustation

Encrustation is a major problem encountered in long-term ureteral stenting with both PSs and MSs. The risk of encrustation is associated with both the stent biomaterial and the patient's history. Encrustation is always related to biofilm formation despite the absence of evident urinary infection. Biofilm is formed by adhesion of micro-organisms on the stent surface and gradual development of a thin film of extracellular matrix around them [28]. Biofilms and urease-producing organisms on a stent surface induce elevation of urinary pH and precipitation of salts such as calcium hydroxyapatite and magnesium ammonium phosphate. The latter process eventually results in struvite and calcium phosphate accumulation [29]. The subsequent encrustation and infection of stents may be responsible for pain, hematuria, and sepsis [30]. The phenomenon of encrustation makes routine exchange of PSs necessary for the prevention of related complications. "Stone formers" are difficult to manage because the exchange intervals are unpredictable [5].

Encrustation of MSs is associated with the aperistaltic segment of the stented ureter in conjunction with ureteral peristalsis and urinary stasis, resulting in encrustation of the areas of the MS uncovered by urothelium [31]. An encrustation-resistant MS needs to be made of

a biomaterial resistant to bacterial infection and subsequent biofilm formation. In addition, it should be easily covered by endothelial cells and become incorporated into the ureteral wall [32, 33].

Urothelial hyperplasia

Urothelial hyperplasia is a significant complication of MS insertion in the ureter. Ureteral patency can be compromised by the development of hyperplastic tissue protruding through the stent struts. The hyperplastic tissue is responsible for restenosis of the stented ureter. An experimental study in a porcine model by Desgrandchamps *et al*. revealed that only one of eight stents was patent 35 days after insertion [34]. It appears that hyperplasia can be prevented by avoiding overextension of the strictured area of the ureter, followed by careful stent implantation. It should be noted that urothelial hyperplasia regresses within 4–6 weeks after MS insertion, resulting in ureteral lumen narrowing [35–39]. Flueckiger *et al*. suggested that the initial effect (first 1–2 weeks) of the inserted MS in the ureter is reactive swelling of the ureter and not hyperplasia of the urothelium leading to constriction of the ureteral lumen [40]. A characteristic trumpet-like morphologic configuration of the ureter located on the upper extremity of the stent has been described, but is not related to ureteral patency risk [27, 39].

Polymeric stents

PSs are the most commonly used ureteral stents and their contribution to urologic practice is invaluable.

A variety of synthetic polymeric compounds has been used for the manufacture of PSs. These materials are based on polyurethane or silicone, such as Silitek (Surgitek, USA), C-Flex (Cook Urological, Spencer, IN, USA), Percuflex (Boston Scientific, Natick, MA, USA) [41, 42]. Silitek is a block copolymer based on silicon, while C-Flex is a proprietary silicone with styrene/ethylene/butylene block copolymer. Percuflex is composed of an olephinic block copolymer. In contrast, Tecoflex (Thermedics, Woburn, MA, USA) is a proprietary aliphatic thermoplastic and is not based on silicone or polyurethane. Polyurethane is a relatively cheap material and has the advantage of high versatility, but its biocompatibility is considered poor and it is related to significantly more urothelial ulceration and erosion [43]. The gold standard of biocompatibility is silicone [44]. Although all the polymeric materials described above are susceptible to encrustation, Siliteck, C-Flex, and Tecoflex are less frequently affected by this complication. Moreover, polyurethane, Silitek, and Percuflex provide high tensile strength [42].

Double-pigtail polymeric stents

The efficiency of retrograde ureteral stenting in obstruction of extrinsic and intrinsic etiology has been reported by Yossepowitch *et al.* [45]. Extrinsic obstruction was associated with a higher degree of hydronephrosis and the site of obstruction was located more distally. Ureteral stents achieved successful alleviation of the obstruction in 94% and 73% of patients with intrinsic and extrinsic obstruction, respectively. Intrinsic obstruction cases were successfully managed at 3 months follow-up, while extrinsic ureteral obstruction was successfully relieved in only 54.6% of the stents after the same time period. Other investigators reported a success rate for retrograde stenting of intrinsic ureteral obstruction of 88%. The mean follow-up was 25.5 months [46]. The experience gained by the same investigators with the management of extrinsic ureteral obstruction by retrograde stenting revealed success rates of 81%, 85%, and 100% for malignant, retroperitoneal fibrotic, and benign etiology obstruction, respectively. Average follow-up was 16 months (range 0.7–98 months) [47].

A large experience with 2431 patients (2685 ureters) who were treated by double-pigtail stent insertion has been recently published [48]. The majority of the indications for ureteral stent insertion were URS or percutaneous lithotripsy, SWL, and open lithotomy. Iatrogenic ureteral injury, extrinsic ureteral obstruction, UPJO, and ureterocysteoneostomy were also managed by double-pigtail stent insertion. Several complications were observed: pain, gross hematuria, bladder irritation, high fever, encrustation, stent migration, and stenosis (or recurrence of stenosis). The mean follow-up period was 31 ± 1.9 days (range 1–123 days). As a result, the insertion of double-J stents for endoscopic and open procedures for upper urinary tract diseases can be considered as a safe and efficient method, at least for up to 4 months.

The long-term outcome of double-pigtail ureteral stenting for the management of extrinsic ureteral obstruction was evaluated by Rosevear *et al*. in a study including experience accumulated over 9 years [47]. In total, 54 patients (87 ureters) with malignant, retroperitoneal fibrosis, or benign tumors were successfully treated in 81%, 85%, and 100% of cases, respectively. The mean follow-up period was 16 months (range 0.7–27 months) and mean interval between stent exchanges was 3.6 months. The average interval to stent failure was 4.8 months (range 0.7–27 months).

Quality of life is an important issue for patients with ureteral stents as the stent-related complications may have a significant impact. Joshi *et al.* investigated the effect of ureteral stents on quality of life and associated urinary symptoms. Storage symptoms, bladder pain, and hematuria were the most common symptoms

observed, and at least one symptom was encountered in 80% of the patients. In addition, the available questionnaires did not elucidate the entire range of symptomatology [19].

A coil-reinforced polymeric double-pigtail stent has been recently introduced for the treatment of malignant ureteral obstruction. The Silhouette stent (Applied Medical, Rancho Santa Margarita, CA, USA) has been introduced due to the high failure rate of common polymeric ureteral stents [6]. The stent proved to be more resistant to extrinsic compression in comparison to the also newly introduced double-J all metal Resonance (Cook Urological) [49].

A unique double-pigtail stent is the Zebra (Neo Medical, Germany). It is a Teflon-coated lumenless double-pigtail stent, which facilitates passage of residual stone fragments through the ureter. The comparison of Zebra to standard PSs in two stone-forming patients who underwent SWL revealed no ureteral damage, and after 4 and 5 weeks there was no encrustation on the Zebra stent, while the standard PSs were covered by considerable encrustation [50]. Moreover, the material fatigue evaluation of the Zebra stent in an experimental model simulating the movement of the ureter estimated that the stent would not break even if were left indwelling for 9 months [51].

Ipsilateral and dual-lumen double-pigtail polymeric stents

The use of two ipsilateral double-pigtail polymeric stents for the management of extrinsic ureteral obstruction resistant to a single stent insertion was proposed almost a decade ago [52]. The first report included five patients who were treated for ureteral obstruction due to ureteral orifice stricture, retroperitoneal fibrosis, and middle ureter stricture. These patients were managed successfully by the insertion of two ipsilateral 7F ureteral stents, which were exchanged at 3-month intervals until the patients were managed surgically [52]. In a subsequent report, malignant ureteral obstruction in seven patients was managed by the insertion of two ipsilateral stents [53]. Previous insertion of a single double-pigtail stent had been unsuccessful in the management of the obstruction. Three patients died within 3 months after the insertion of the two ipsilateral stents, while the remaining four had a mean follow-up of 16 months (38 months maximum). Stents were exchanged every 4–6 months to avoid long-term complications.

A novel dual-lumen double-pigtail stent composed of two adhered ureteral stents has been evaluated in a porcine model. The stent provides better flow in comparison to a single ureteral stent. The main advantage of this stent is that its insertion requires only one guidewire, whereas insertion of two ipsilateral stents requires two guidewires, making the procedure more cumbersome [16].

Biodegradable polymeric stents

Biodegradable polymeric materials and stents have been proposed in urology for over a decade. Their main advantage is that they do not need to be removed. An additional procedure for the extraction of the inserted stent is not necessary, the complications of this procedure are avoided, and the period of discomfort for the patient is shortened [6, 42].

In a porcine model, a PLGA ureteral stent inserted after experimental Acucise™ balloon incision endopyelotomy was shown to provide similar drainage to a standard PS (Applied Medical) in pigs, but its biocompatibility was not favorable compared to a standard stent since the musculature of the incised ureteral segments revealed inferior healing [54].

A biosolvable ureteral stent (TUDS; Boston Scientific) was evaluated in terms of biodegradation and biocompatibility in a porcine model. The stent is designed to maintain ureteral patency for 48 h, after which it softens and eventually degrades. Histologic results were similar for both a standard hydrogel-coated stent and TUDS [55]. The clinical assessment of the TUDS stent showed safe and efficient drainage. Dissolution took place in 90% of the stents after an average of 8 days. Satisfaction was reported by 89% of the patients treated by TUDS [56].

Tajla *et al*. evaluated a horn-shaped helical PGLA stent that was used for the postoperative management of antegrade endopyelotomy (cold-knife technique) performed for UPJO [57]. *In vitro* studies estimated the degradation time for the stent to be 2–2.5 months. Percutaneous nephrostomy or stent removal procedures were not deemed necessary for the treated patient. The stent contributed to the reduction of vesicoureteral reflux and postoperative renal infection due to its function as a partial catheter.

Drug-eluting and drug-coated polymeric stents

Recently, polymeric ureteral stents that are coated with pharmaceutical substances or release drugs from their surface to the surrounding tissue have been introduced and clinically tested. Triclosan is a broad-spectrum antibacterial and antifungal agent which has been reported to inhibit the growth of common bacterial uropathogens *in vitro*, and is thus considered useful for the reduction of urinary tract infection and subsequent encrustation of an indwelling stent [58]. A significant decrease in *Proteus mirabilis* growth and survival was observed in a rabbit experimental model when a triclosan-eluting ureteral stent was inserted in the urinary system (bladder)

[59]. In eight patients significantly fewer antibiotics were administered, and there was a slightly higher number of positive urine cultures, but significantly fewer symptomatic infections with long-term use of the triclosan-eluting stent. Bacterial resistance to triclosan was not noted during the 3-month follow-up period [60].

A recently introduced ketorolac-eluting stent was evaluated for its short-term efficacy in a double-blind randomized multi-institutional clinical trial [61]. The 276 patients included were divided into two groups (triclosan stent and conventional stent). There were no significant differences in primary and secondary intervention rates between the two groups. Fewer patients with the ketorolac-eluting stents used pain medication in comparison to the control group.

A heparin-coated double-pigtail ureteral stent was introduced in an attempt to minimize microbial adhesion, biofilm formation, and subsequent encrustation of long-term indwelling stents in the urinary tract. In five patients, a heparin-coated ureteral stent was inserted in one ureter and a conventional double-pigtail stent in the other for a month [62]. The thickness of the encrustations observed by electron microscopy on the heparin-coated stents was significantly less in comparison to that on the conventional ureteral stents. Moreover, the encrustation on the heparin-coated stents was less uniform and more compact. Two heparin-coated stents were left indwelling long term (10 and 12 months) and on removal showed no evidence of encrustation and an unchanged heparin layer.

Metal mesh stents

Self- and balloon-expandable metal mesh stents

MSs used in the ureter can be divided into four general groups: self-expandable, balloon-expandable, covered, and thermo-expandable shape-memory stents. Covered MSs were introduced in an attempt to minimize tissue ingrowth, which eventually compromises ureteral patency [27]. MSs implanted in the ureter for the management of various malignant and benign diseases are the Wallstent (Microvasive, Natick, MA, USA), Memokath 051 (Engineers & Doctors A/S, Kvistgaard, Denmark), self-expanding polytetrafluoroethylene-covered nitinol stent (Hemobahn Endoprosthesis, W.L. Gore and Associates, Flagstaff, AZ, USA), and the recently introduced all-metal double-pigtail Resonance stent (Cook Urological).

The Wallstent is composed of braided biomedical cobalt-based alloy monofilaments and is the most extensively used self-expandable endoprosthesis in the ureter [1]. Inserted in the ureter it appears to represent a safe and effective method for the palliative treatment of malignant ureteral strictures. Benign and malignant ureteral strictures in patients not suitable for surgical treatment were treated with the Wallstent by Pollak *et al*. [63] One of six stented ureters were patent after 11 months. In two patients, three stents were implanted for the palliative management of malignant disease and were patent up until death (3–5 months after implantation). Ingrowth of hyperplastic and granulation tissue was responsible for the occlusion of all stents inserted for benign strictures, while tumor ingrowth and granulation tissue were observed in malignant cases. Wallstent endoprosthesis proved to be ineffective for long-term drainage in patients with benign ureteroenteric strictures . The mid-term clinical outcome of the Wallstent self-expandable stent implantation for the management of malignant ureteral obstruction was evaluated in 40 patients with 54 malignant ureteral obstructions [37]. Patency was confirmed in 51 of the stented ureters during the mean follow-up period of 10.5 months (range 1–44 months). Almost half of the ureters (49%) required additional procedures to maintain patency. Adequate drainage preventing hydronephrosis was observed in the majority of the cases and major complications were not encountered.

Malignant ureteral strictures due to gynecologic cancer were managed in 14 patients with self-expandable MSs in a report by Barbalias *et al*., and ureteral obstruction was relieved in all cases [64]. The mean follow-up time was 15 months (range 9–24 months). Tumor ingrowth requiring additional coaxial stent placement and borderline tumor overgrowth were observed in one case each. Urothelial hyperplasia was noted in all stented ureters and additional retrograde insertion of a double-pigtail stent was deemed necessary for a 1-month period. On the proximal edge of the stent, a mild ureteral narrowing was noted (trumpet-like configuration), which did not impact ureteral patency. The trumpet-like configuration was a constant finding during the follow-up period. The authors concluded that the implantation of self-expandable MSs is a safe and effective method for by-passing gynecologic malignant ureteral obstruction.

The combination of self-expandable MSs with coaxial double-pigtail stents was proposed by Hekimoglou *et al.* [31]. Ten ureters (10 patients) with malignant obstruction were treated with this combination. The double-pigtail stents were removed in seven patients 2 and 3 months after the implantation. Six patients developed hydronephrosis and double-pigtail stents were reinserted. PS exchange was performed at 3-month intervals. The MS lumen was compromised by hyperplastic tissue and encrustation. Nevertheless, this combination was adequate to achieved internal urinary drainage.

Several authors have reported promising results with the management of ureteroileal anastomotic strictures by MS insertion [17, 65–72]. In these reports between 1 and 18 patients were treated, while the number of

treated ureteroileal strictures ranged between 1 and 24. The mean follow-up period ranged from 6 to 22 months. Stricture recurrence was observed by the majority of the authors. Our group reported long-term results in 18 patients with ureteroileal anastomotic strictures who were managed with MS placement [17]. Mean follow-up was 21 months (range 7–50 months). The technical success rate of stricture crossing and stenting was 100%. Immediate poststenting patency rate was 70.8% (17 of 24 cases), while primary patency rates at 1 and 4 years were 37.8% and 22.7%, respectively. Fifteen stented ureters required secondary interventions. Secondary patency rates were 64.8% and 56.7% at 1 and 4 years, respectively. Periodic exchange of external–internal double-pigtail catheters until the end of the follow-up period was performed in six ureteroileal conduits. Definitive treatment for the ureteroileal strictures was achieved by MSs in more than half of the cases. The remaining cases were managed by regular exchange of double-J catheters in retrograde fashion. Surgical revisions of ureteroileal anastomotic strictures are challenging, while MS implantation provides efficient drainage while preserving the quality of life.

Barbalias *et al*. have proposed the use of self-expandable MSs for the management of UPJO [18]. MSs were placed in four patients who had previously undergone open pyeloplasty and in whom recurrence of UPJO was diagnosed. The mean follow-up period was 16 months (range 9–24 months). The placement procedure was successful in all cases and patency was confirmed in all four patients. Ingrowth of fibrotic tissue through the stent led to additional coaxial overlapping MS insertion in one patient 2 months after initial stent placement. The results were promising and the authors suggested the performance of more extensive clinical trials in order to validate this application of MSs.

Balloon-expandable stents have not been extensively used in the ureter. Barbalias *et al*. treated six patients with malignant disease with self-expanding stents and six with balloon-expandable stents [36]. Additional interventions were deemed necessary in three cases due to urothelial hyperplasia, tumor ingrowth, and local recurrence of primary cancer invading the upper end of the ureter. Mean follow-up was 9 months (range 8–16 months).

Memokath 051 represents a unique type of MS. It is a thermoexpandable shape-memory stent composed of nickel and titanium alloy. It has a tight spiral structure, which prevents urothelial growth [73]. The Memokath 051 softens below 10 °C and regains its shape when reheated to 50 °C. The thermal shape memory feature makes the removal of the stent possible. Kulkarni and Bellamy have used the endoprosthesis for the management of ureteral obstruction of both benign and malignant etiology [74]. Long-term results for the management of malignant and recurrent benign strictures are available: 18 malignant and 10 recurrent benign cases were treated with the Memokath 051 and followed up for a mean of 19.3 months (range 3–35 months). At the end of the follow-up period, 15 stents (13 patients) provided adequate drainage, while eight patients carrying 13 functioning stents had died. Infection and migration were not observed. In general, the Memokath 051 proved to be advantageous over conventional double-J catheters. Moreover, the potential for removal of the stent due its thermal memory was a significant advantage over conventional MSs. This removal capability was not a feature of any other MS until the introduction of the Resonance double-pigtail MS.

Such favorable results with the Memokath 051 were not reported by Klarskov *et al*., who used it to treat 37 stenosed ureters (33 patients) attributed to both malignant and benign conditions [75]. The mean follow-up period was 14 months (range 3–30 months). Migration towards the bladder was observed in 10 stents and 12 stents malfunctioned, giving a total of 22 nonfunctioning MSs. Encrustation resulted in occlusion of four stents at intervals after stent insertion ranging between 1 and 10 months.

Li *et al*. evaluated a titanium–nickel alloy-based self-expandable stent in benign ureteral strictures over a long mean follow-up period of 92 months (range 12–131 months) [76]. Encountered complications included hyperplastic reaction, infection, and encrustation with stone formation. The investigators concluded that MSs could adequately manage selected cases of ureteral strictures.

Recently, we reported our 10-year experience with metal mesh stenting for the management of malignant ureteral obstruction [77]. Ninety patients (119 ureters) with ureteral obstruction from various pelvic and metastatic tumors were treated with several different types and brands of MSs in an attempt to provide long-term urinary drainage without requiring nephrostomy tubes, and followed up for a mean of 15 months (8–38 months). Hyperplastic reaction and/or tumor ingrowth resulting in tissue protruding through the stent struts and obstructing the stent lumen was the most common problem and was addressed by repeat balloon dilations. Those cases resistant to balloon dilation were managed by insertion of a double-pigtail stent coaxially, which assured ureteral patency. With primary and secondary patency rates of 51.2% and 62.1%, it was concluded that metal mesh stenting of the ureter should be carefully considered for long-term urinary drainage.

Covered metal mesh stents

Covered MSs were introduced as a solution to the urothelial hyperplasia compromising the patency of

conventional MSs. The high migration rate (81.2%) of covered MSs, which could induce renal colic, represented a major problem in clinical application and minimized further use of these stents in the urinary tract. The inability of covered MSs to anchor into the ureteral wall was associated with the coating material and the enhanced ureteral peristalsis [27]. Migration was managed by cystoscopic removal of the migrated covered stents and the coaxial insertion of bare stents.

Recently, an S-shaped covered MS was introduced and underwent comparative evaluation to bare MSs in the canine ureter. The shape of the stent was responsible for the anchoring into the ureteral wall. The stent was covered with polytetrafluoroethylene (PTFE) for prevention of lumen occlusion due to hyperplastic reaction. Both migration and the hyperplastic ureteral obstruction were avoided [78]. Clinical investigation with this stent will help to clarify the controversial results with covered MSs.

Double-pigtail metal stents (Resonance)

The Resonance stent (Cook Urological) was recently introduced as an all-metal double-pigtail stent. It is composed of MP35N alloy (nonmagnetic nickel–cobalt–chromium–molybdenum alloy) in a tight spiral structure. Ureteral obstruction, due to either malignant or benign conditions, can be managed with Resonance [79–82]. Borin *et al*. were the first to report a case of Resonance stent insertion and successful management of ureteral obstruction due to retroperitoneal fibrosis from metastatic breast cancer [79]. The obstruction had not been controlled by the previous insertion of two 6F double-pigtail PSs. The ureter was patent over a 4-month follow-up period. Resonance stent insertion was used to manage malignant ureteral obstruction without bulky pelvic disease in 15 patients (17 ureters) who were followed up for between 1 week and 8 months [80]. In three patients, the initial stent was exchanged after 6 months and after 12 months in one patient. Long-term drainage of the obstructed ureters was reported to be efficient and encrustation was minimal. Stents were patent and functioning in four patients who were still alive at the end of the follow-up period. The Resonance stents were not removed in seven patients who died during the follow-up period. Nagele *et al*. treated 14 patients (18 ureters) with ureteral obstruction of either benign (n = 5) or malignant etiology(n = 13) [81]. Mean follow-up was 8.6 months. Encrustation was evident on two stents. Seven stents were removed due to persistent hematuria, severe dysuria, pain, and inadequate drainage. In an attempt to ensure patient comfort, an appropriate stent length should be selected. In addition, satisfactory drainage under circumstances of extrinsic ureteral obstruction was confirmed by an experimental study. Nevertheless, less overall flow than with a standard PS was noted for the Resonance stent [83].

Our group assessed in a porcine model the effect of SWL or radiotherapy on ureters with an indwelling Resonance stent. The histologic deterioration of pig ureters stented with Resonance was not significant compared to control ureters (standard stents) after SWL or radiotherapy, and ureteral temperature was not detected to be significantly higher for the Resonance ureters [84, 85].

The clinical efficiency of Resonance was evaluated by our group in a clinical trial including 50 patients with malignant or benign ureteral obstructions [82]. All cases of extrinsic obstruction due to malignant factors were managed adequately (25 patients), while patency was observed in 44% of the benign intrinsic obstruction cases (25 patients). The benign case group included patients with lithiasis, ureteroileal obstruction, iatrogenic strictures, or an occluded ureteral MSs and who were contraindicated for any surgical or endoscopic procedures due to comorbidities. Further clinical trials are deemed necessary to clarify the indications for the insertion of the Resonance stent. Average overall follow-up was 8.5 months (range 4–14 months), and the mean follow-up for malignant and benign cases was 11 months and 6.8 months, respectively. The removed Resonance stents underwent laboratory investigation to identify the presence of encrustation and the type of deposits. Encrustation was evident in 20% of the extracted stents. The most common location of enscrustation was the edges of the stent. Even stents without evident encrustation were observed to have deposits on scanning electron microscopy (Figures 67.1). Calcium oxalate was the most frequent encrustation deposit.

The clinical application of the Resonance stent in ureteroenteric strictures was reported to be unsuccessful by Garg *et al*., who inserted it for the management of 10 strictures in 10 patients with ileal conduits [86]. Distant migration was observed in nine cases in a mean of 21 days (range 3–60 days). More recently, Lopez-Huertas *et al*. managed 13 patients with benign upper urinary tract ureteral obstructions with the Resonance stent (15 stents) [87]. The majority of the stents provided adequate drainage and 12 patients were efficiently managed. The stents were removed in three patients who showed voiding symptoms such as hematuria. The remaining patients had their stents exchanged after a mean follow-up of 11.6 months. The investigators also conducted a cost-effectiveness analysis and reported a significant cost reduction in favor of the Resonance stent.

Drug-eluting metal mesh stents

Interventional cardiology has gained significant experience with drug-eluting MSs (DESs). In fact, the DESs

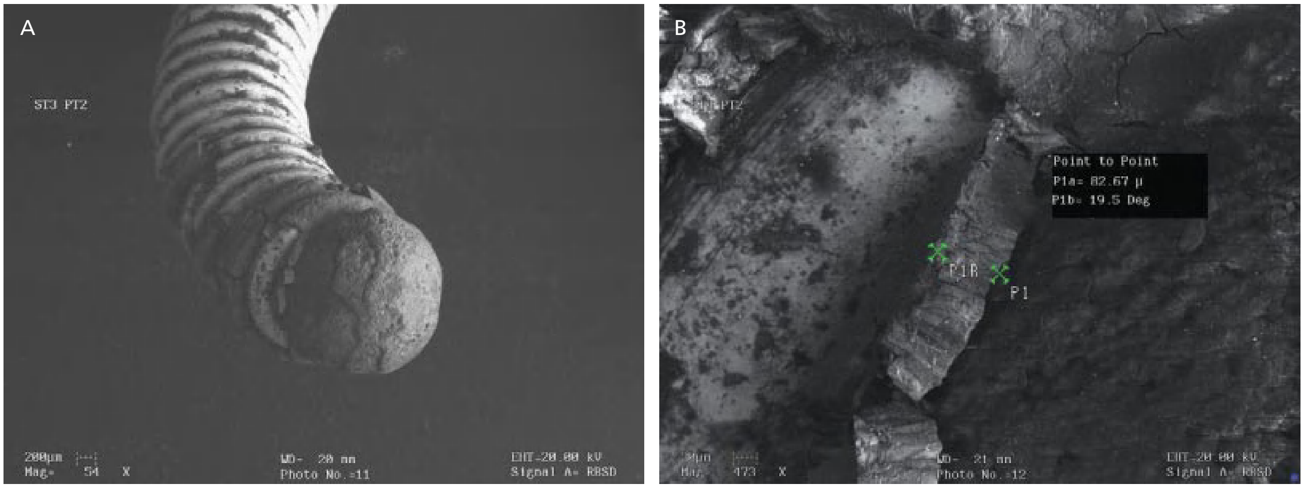

Figure 67.1 (A) Scanning electron microscopy image obtained from the lower extremity of a Resonance stent that was indwelling for 9 months. Note the encrustation layer, which was barely visible macroscopically. (B) Same Resonance stent at higher magnification. The crystals of the encrustation deposits are visible.

represent the most commonly used stents in this specialty. The concept of DESs is to minimize or even eliminate the reaction of the coronary tissue to the stent, which is responsible for platelet adhesion (activation of coagulation cascade) and neointimal hyperplasia [88]. The use of DESs in the ureter is currently limited to experimental animal studies, which have demonstrated reduction of ureteral tissue hyperplasia. Our group has investigated the effect of the paclitaxel-eluting stent in porcine ureters (10 pigs in total). A DES was inserted in one ureter and a bare MS in the other ureter of each animal. Over a follow-up period of 21 days, the majority of MSs were occluded and the remaining MSs were stenosed by hyperplastic reaction, while all the DESs were patent [89]. Recently, we evaluated zotarolimus-eluting MSs (Endeavor; Medtronics, Minneapolis, MN, USA) in porcine and rabbit models. Three weeks after placement we observed less hyperplastic reaction in the DESs in comparison to the bare MSs, which were used as the control in the contralateral ureter of the same animals (unpublished data) (Figure 67.2). The effectiveness of DESs in these animal models is promising for their clinical application.

Outcome of long-term ureteral stenting

The long-term use of ureteral stents currently represents a challenge for biomaterial science, pharmacology, and urologic research [1]. The frequent exchange of double-pigtail PSs is accepted clinical practice, with complications addressed by pharmaceutical therapy or additional interventions, and these stents should not be expected to be in place for longer than a few months. While cases

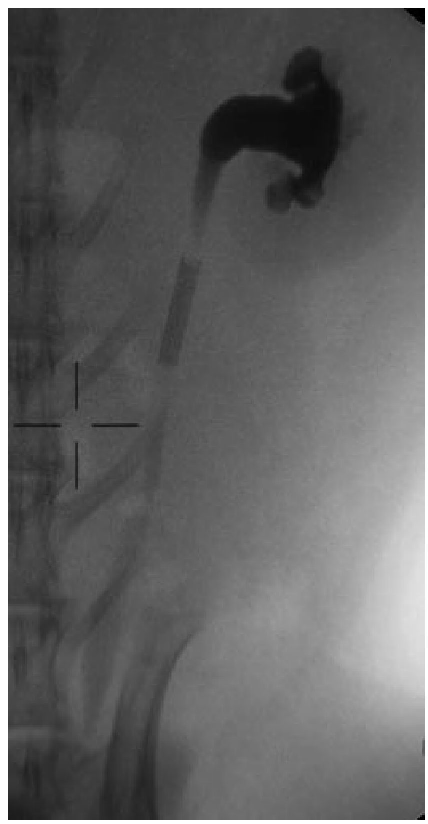

Figure 67.2 Fluoroscopic image of a zotarolimus metal stent a week after its insertion in a rabbit ureter. Note the trumpet-like configuration on the ureter segment located at the upper extremity of the stent. The configuration did not influence the patency of the stent. Note the lack of hyperplastic reaction in the lumen of the stent.

of ureteral PSs indwelling for longer periods (even years) have been reported, and several methods proposed for their extraction, they are challenging cases and represent a “headache” for the urologist [90]. Clinical experience with biodegradable PSs remains limited and further refinement is necessary for the wide acceptance of these stents [1]. The development of newer biodegradable materials could lead to the introduction of new biodegradable stents. Drug-eluting and drug-coated PSs are rapidly evolving and their first clinical application appears promising. Moreover, the potential of the latter stent type could be increased with the countless pharmaceutical substances that could be used on their surfaces.

MSs are a completely different category of stent and are used significantly less frequently in urologic practice. Nevertheless, experience has accumulated over the years. Long-term results have proved to be poor despite the initial promising outcome [1, 77]. Thus, patients should be carefully selected for stenting with an MS. The first MS with a double-pigtail design provides adequate drainage in cases of PS failure and has shown excellent results in long-term management of malignant ureteral obstruction. In contrast, benign cases have been associated with unfavorable results. Further clinical investigations will elucidate the true efficacy and indications for these stent [82]. DESs are the next step in the evolution of metal stenting in the ureter. These stents have a tremendous impact in interventional cardiology. Their use to overcome the difficulties encountered during metal stenting is expected. Available experimental reports are rare but still promising regarding the possible outcome in clinical trials.

SECTION 6
Laparoscopy and Robotic Surgery

CHAPTER 68
Patient Preparation and Operating Room Set-up for Laparoscopic and Robotic Surgery

Sarah P. Conley & Benjamin R. Lee
Tulane University School of Medicine, Department of Urology, New Orleans, LA, USA

Introduction

Laparoscopic and robot-assisted procedures have become the cornerstone of a urologist's surgical armamentarium over the past two decades. These minimally invasive procedures require additional equipment and operating room set-up. Patient and operating room preparation are key features to successful and efficient surgery.

It is imperative that the operating room personnel and surgeon are familiar with all equipment systems and proper preparation of equipment. Urology surgical team members also need to be able to troubleshoot unexpected occurrences during a case. Without proper preparation and positioning, patient safety and surgical outcomes may be compromised. In this chapter we describe key features of patient preparation and operating room configuration for common laparoscopic and robotic surgeries.

Patient preparation

Careful patient selection for minimally invasive urologic procedures is critical for successful outcomes. Patient selection begins with a thorough history and physical examination, including attention to cardiopulmonary status and previous abdominal surgeries. Medical and/or cardiovascular clearance may be warranted. Patients with chronic obstructive pulmonary disease require pulmonary clearance, including pulmonary function tests, because of the risk of hypercarbia. Appropriate laboratory data, such as complete blood count, basic metabolic panel, prothrombin time, partial thromboplastin times, and urinalysis with culture should be considered. Radiologic imaging is helpful for surgical planning. For example, computed tomography (CT) with intravenous contrast is valuable for delineating the renal vascular supply for laparoscopic nephrectomy or partial nephrectomy, or for identifying crossing vessels prior to pyeloplasty.

The indications for laparoscopic and robotic urologic procedures are almost identical to those of open surgery. Absolute contraindications to minimally invasive surgery include uncorrectable coagulopathy, abdominal wall infection, massive hemoperitoneum, and generalized peritonitis [1]. Intestinal obstruction was formerly considered an absolute contraindication; however, many general surgeons will perform diagnostic laparoscopy for small bowel obstruction if the bowel is not too dilated. Historically, relative contraindications to minimally invasive surgery included morbid obesity, extensive prior abdominal/pelvic surgery, pelvic fibrosis, organomegaly, ascites, pregnancy, hernias, and iliac or aortic aneurysms. However, in this current day and age laparoscopic and robotic surgery can be safely performed in patients with morbid obesity and previous abdominal surgery with minor technical adaptations. For example, trocar placement for laparoscopic renal surgery can be shifted laterally for obese patients and the Veress needle can be introduced off site from abdominal scars in patients with previous abdominal incisions during initial insufflation. Pregnancy is no longer considered a contraindication for laparoscopy.

Smith's Textbook of Endourology, Third Edition. Edited by Arthur D. Smith, Gopal H. Badlani, Glenn M. Preminger, Louis R. Kavoussi.

Informed consent

All patients should understand the risks, benefits, and alternatives of the proposed procedure. Complications associated with minimally invasive procedures are similar to their open counterparts with the exception of a few unique complications, including CO_2 embolism, hypercarbia, postoperative crepitus, and shoulder pain from pneumoperitoneum. Every patient who undergoes a laparoscopic or robotic procedure should understand the potential for conversion to an open procedure and this should be documented in the written consent.

Consent for blood products

For surgeons who have experience with laparoscopy, blood type and screen can be sufficient for most minimally invasive urologic procedures. Type and cross for 2 units of packed red blood cells is appropriate for more extensive procedures, such as partial nephrectomy and radical cystectomy. We do not recommend preoperative donation of autologous blood prior to robot-assisted radical prostatectomy because of lower estimated blood loss due to pneumoperitoneal compression of venous blood supply with the laparoscopic approach [2].

Bowel preparation

Preference for bowel preparation varies from surgeon to surgeon. It is our recommendation that patients take a half bottle of magnesium citrate for transperitoneal laparoscopic or robotic renal procedures and that radical prostatectomy patients additionally administer a Fleet enema on the morning of surgery. Many minimally invasive urologic surgeons do not routinely administer a bowel preparation prior to laparoscopic or robotic renal or prostate surgery.

Our preference for bowel preparation prior to robot-assisted radical cystectomy is mechanical bowel preparation only with an oral electrolyte solution. We no longer routinely administer antibiotic bowel preparation (i.e. oral neomycin and metronidazole); however, broad-spectrum antibiotics are administered intravenously within 60 min of incision.

Operating room set-up

Operating room set-up, experienced nursing staff, and a team approach are keys to a smooth procedure. All operating room personnel should be familiar with the operating room set-up and basic equipment function. Minimally invasive procedures require more equipment than standard open procedures; thus, the operating room should be large enough to accommodate the laparoscopic tower and the robotic system.

Table 68.1 Basic equipment for laparoscopic surgical procedures.

Mobile video cart with monitor
Secondary video cart
CO_2 insufflator with CO_2 tank or wall supply
CO_2 insufflation tubing
Camera, high-resolution and control box
0° and 30°, 5- or 10-mm laparoscopes
Scope warmer
High-intensity light source
Fiberoptic light cable
Electrosurgical cords
Electrosurgical unit with foot pedal (LigaSure, monopolar, Harmonic scalpel)
Aspiration–irrigation system with double canister suction apparatus
Two S-shaped retractors
Two Allis clamps
DVD recorder (optional)

All equipment should be tested prior to each procedure to make sure it is functional, including the aspiration–irrigation system, electrocautery, CO_2 insufflation, camera, and light source. The argon beam electrocautery or saline-enhanced radiofrequency cautery should also be tested prior to partial nephrectomy. Lists of equipment necessary for laparoscopic and robotic renal surgery, as well as robotic pelvic surgery, are given in Tables 68.1–68.3. An open tray should be either set up or immediately available in the room in the event rapid conversion to open surgery is needed.

The room configuration for renal surgery varies from left to right side and from laparoscopic to robotic cases. Aerial diagrams of room set-up for laparoscopic transperitoneal renal surgery and robotic pelvic surgery are shown in Figures 68.1–68.3.

Most laparoscopic renal surgeries are performed with the surgeon and assistant on the same side of the table. Thus, two video monitors are ideal with the main laparoscopic tower (containing video monitor, light source, camera, and insufflators) placed on the side opposite the surgeons. The CO_2 insufflator is placed within the surgeon's view to allow for continuous monitoring of the intraperitoneal pressure. The second video tower is placed in view of the second assistant and the scrub nurse who are stationed on the side opposite the surgeons along with the instrument table. Incoming lines from the camera, light cord, CO_2 insufflation tubing, aspiration–irrigation tubing, and electrosurgical devices

Table 68.2 Equipment for laparoscopic renal surgery.

One Veress needle	Two 5-mm atraumatic grasping forceps (blunt)
	One 45-mm endovascular stapler
One 5-mm trocar	Two endovascular stapler reloads
Two 12-mm trocars	One laparoscopic monopolar scissors, Harmonic scalpel, LigaSure (Covidien, Boulder, CO, USA)
One aspiration–irrigation tubing and probe	
Additional equipment for laparoscopic partial nephrectomy	
Four bulldog clamps with remover	FloSeal Hemostatic Matrix (Baxter, Deerfield, IL, USA)
One Satinsky clamp	Hem-o-lok ligation system (Teleflex Medical, Research Triangle Park, NC, USA)
Additional 12-mm trocar for assistant	Lapra-Ty absorbable suture clips (Ethicon, Somerville, NJ, USA)
Laparoscopic ultrasound	2-0 polyglactin CT-1 suture
0-vicryl CT-1 x 3	Closed suction drain
Closed suction drain	

Table 68.3 Equipment for robot-assisted laparoscopic radical cystectomy.

One Veress needle	One laparoscopic scissors
Three 8-mm robotic trocars (for daVinci S, Si, or fourth arm)	Hem-o-lok ligation system (Teleflex Medical, Research Triangle Park, NC, USA)
Two 12-mm trocar	One 10-mm titanium clip applier (optional)
One 5-mm trocar	One 2-0 polyglactin CT-1 suture cut to 10 inches for dorsal vein stitch
One aspiration–irrigation tubing and probe	One 3-0 RB-1 cut to 6 inches for posterior reconstruction stitch (optional)
Robotic monopolar scissors	Two 3-0 UR-6 tied together as a “double-armed” stitch, cut to 7 inches each
Robotic bipolar Maryland grasper	One 3-0 RB-1 available for anterior bladder neck reconstruction
Robotic prograsp	One 10-mm Endocatch bag
Robotic fenestrated bipolar electrocautery (optional)	One 18F Foley catheter (intraoperative catheter)
Robotic Harmonic scalpel (optional)	One 20F Foley catheter (final catheter)
One 5-mm atraumatic grasping forceps	Closed suction drain
One laparoscopic needle driver	
Additional equipment	
30° down camera lens	
One 15-mm trocar for assistant	
One 12-mm trocar for assistant	
Laparoscopic LigaSure (Covidien, Boulder, CO, USA)	
Laparoscopic endovascular stapler (optional)	
Open tray for urinary diversion	

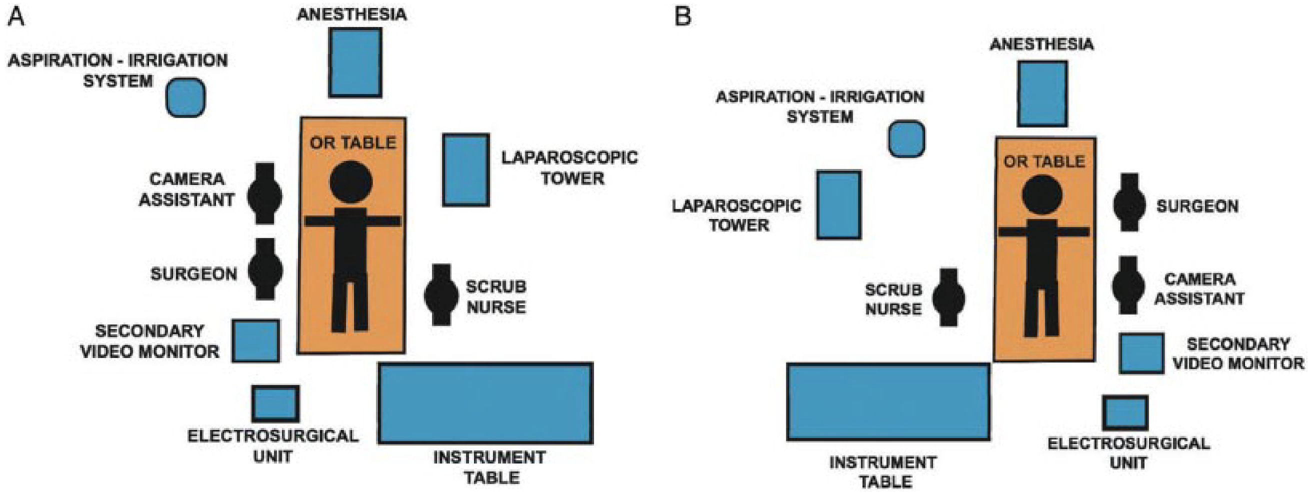

Figure 68.1 Operating room set-up. (A) Left-sided laparoscopic transperitoneal renal surgery. (B) Right-sided laparoscopic transperitoneal renal surgery.

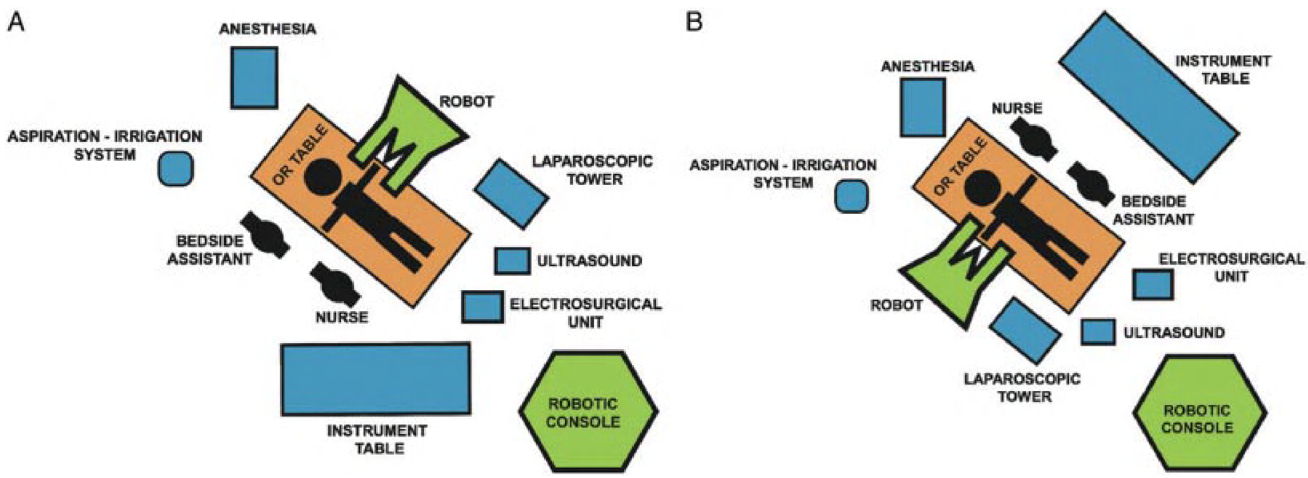

Figure 68.2 Operating room set-up. (A) Left-sided robotic transperitoneal renal surgery. (B) Right-sided robotic transperitoneal renal surgery.

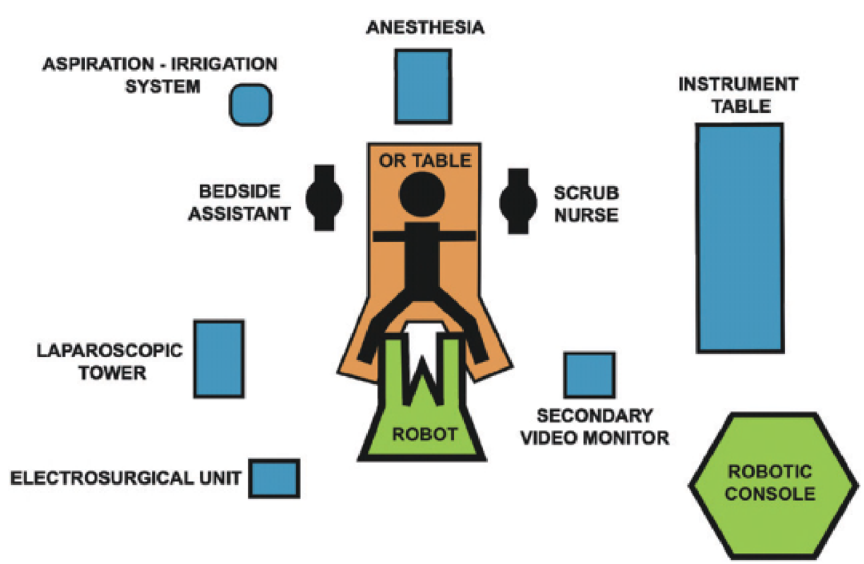

Figure 68.3 Operating room set-up for robotic pelvic surgery.

enter from the contralateral side of the table or from the head or foot of the table. Additional lines from equipment, such as a Harmonic scalpel, LigaSure (Covidien, Boulder, CO, USA) or argon beam coagulator, should be arranged in an orderly fashion to prevent them from getting tangled during surgery. Pre-existing or improvised pockets in the laparoscopic drape can be helpful for organizing equipment.

During robotic procedures the surgeon console can be positioned in a corner of the operating room, depending on room configuration. In the newer generation robotic surgical systems, the optical viewer, arm rest, and foot pedals can be easily adjusted for surgeon comfort. For robotic renal surgery, the assistant is positioned on the side opposite the surgical site. For robotic pelvic surgery, the authors' preference is for the bedside assistant to sit or stand on the patient's right side with the scrub nurse on the patient's left side. One advantage of having the scrub nurse and assistant on opposite sides of the table is that the scrub nurse can be positioned close enough to the table to actively participate in the surgery, such as during Foley catheter manipulation and for applying perineal pressure. A disposable plastic instrument holder can be secured to the laparoscopic-assisted vaginal hysterectomy (LAVH) drape next to the bedside assistant for convenient intraoperative storage of frequently used instruments. This helps minimize instrument passage across the patient's body. Alternatively, a sterile Mayo stand can be positioned next to the bedside assistant as a "mini table" to hold the frequently used instruments. It should be noted that some surgeons prefer the bedside assistant to be located on the patient's left side, allowing the fourth arm to be placed on the patient's right side and the two grasping instruments to be used simultaneously. A second video monitor is helpful for the remainder of the operating room staff. If laparoscopic ultrasound is used, the screen should be placed within the assistant's direct line of vision.

Once the robotic and assistant ports are placed, the robot is docked. It is important to align the base of the slave unit with the camera port. This allows for proper docking of the robotic instruments in order to have adequate range of motion and to avoid arm collisions. With the daVinci Si Surgical System, it is important that the blue arrow on the camera arm be aligned within the "sweet spot" to ensure the slave unit is docked within the correct distance from the operating table to accommodate appropriate range of motion of all instruments.

Patient positioning

Laparoscopic renal surgery

In traditional open renal surgery, the patient is positioned in flank position in the lateral decubitus position with the kidney rest elevated and the table flexed. In contrast, laparoscopic transperitoneal renal surgery can be effectively performed with the patient in the modified flank position [3] (Figure 68.4). The patient is placed in the supine position with a 10 lb sandbag or gel roll under the ipsilateral side, creating a 30º rotation. The bottom leg is slightly bent and the top leg is left straight. Pillows are placed between the legs as a cushion and to slightly elevate the upper leg in line with the torso. The chest and hips are secured to the table with 3-inch silk tape. The ipsilateral arm is then padded and secured in a modified "sling" position, similar to the position used by orthopedics for clavicular fractures. The contralateral arm should be secured to an arm board. All pressure points are padded with corrugated foam or gel pads. Neither the kidney rest nor an axillary roll is necessary in this modified flank position. The table is then maximally rotated laterally, thus creating a true 90º angle relative to the horizontal. The lateral rotation of the bed should be tested prior to draping the patient and the anesthesia team should ensure patency of arterial and venous access. This positioning is ergonomic for the patient and surgeon.

Figure 68.4 Patient positioned in modified flank position for laparoscopic and robotic transperitoneal renal surgery.

Positioning for retroperitoneal laparoscopic renal surgery is similar to that for open nephrectomy. The patient is placed in the full lateral position in the center of the table with the kidney rest elevated and the table flexed. An axillary roll is placed to prevent brachial plexus injury.

Bilateral lower extremity antiembolic stockings and pneumatic compression devices should be in place prior to induction of anesthesia. An upper body and/or lower intraoperative warming device should be placed before the patient is prepped and draped. There is debate about optimal surgical site preparation and preoperative

antibiotics for prevention of incisional infections. A recent prospective randomized clinical trial comparing chlorhexidine–alcohol to povidone–iodine for surgical site preparation demonstrated a statistically significant reduction in both superficial and deep surgical incisional infections with the use of chlorhexidine–alcohol [4]. The entire abdominal wall should be prepped from the nipples to the pubis. The genitalia should be prepped in the field for minimally invasive nephroureterectomy and ureteral reimplant to allow for sterile Foley catheter placement on the field. Antibiotic prophylaxis should be administered within 60 min of the surgical incision. The American Urological Association's best practice policy statement on urologic surgery antibiotic prophylaxis is an excellent resource for selecting specific preoperative antibiotics [5]. Prior to insufflation, an orogastric tube and Foley catheter should be in place in order to decompress the stomach and bladder to avoid inadvertent injury to these hollow viscera.

Robotic pelvic surgery

For robotic pelvic surgery the patient is ultimately placed in a steep Trendelenburg position with the legs in a low lithotomy position (Figure 68.5). This position allows gravity to pull the abdominal viscera away from the operative field and the assistant to access the perineum and genitalia intraoperatively. The operating table is prepared with egg-crate foam taped to the table and a folded sheet placed under the egg-crate foam to facilitate securing the arms. The friction between the egg-crate foam and the patient's skin will help prevent cephalad slippage or movement when the table is in the full Trendelenburg position. Some centers advocate the use of a gel pad instead of egg-crate foam between the operating table and the patient's skin because of reports of chafing and skin breakdown. The patient is placed in the supine position with the buttocks at the end of the table break. Prior to induction of anesthesia, compression stockings and sequential compression devices are placed on the patient's lower extremities. The legs are placed in Allen Yellofin stirrups (Allen Medical Systems, Acton, MA, USA) with the knees flexed. The foot of the table is then lowered until it is perpendicular to the floor. Care should be taken to align the toe, knee, and opposing shoulder, to ensure the heels are touching the heel of the boot, and to check that the calves have adequate space to avoid popliteal artery occlusion, peroneal nerve injury [6], or the devastating complication of lower extremity compartment syndrome [7]. The anesthesiologist should evaluate the position of the patient's head before and after applying the Trendelenburg position in order to monitor for slippage. The arms are tucked at the patient's side with the preplaced sheet under the gel pad. Alternatively, arm sleds can be utilized to secure the arms without tension; however, excess arm compression can result in temporary neuropraxia. The fingertips are positioned at the anterolateral thigh. The elbows and wrists are protected with gel padding, and small foam rolls are placed in the patient's hands. Care should be taken to ensure that vascular lines and the pulse oximeter are properly functioning. The arms should be secured low enough for the prepped field to include the area lateral to the anterior superior iliac crest. Obese patients may require an arm board on the side of the table to support the arms. We do not recommend routine use of shoulder straps or taping the shoulders in a harness fashion because of the risk of brachial plexus injury [8, 9]. We recommend using foam-wrapped 3-inch cloth tape across the chest to prevent cephalad slippage in obese patients only. Care should be taken to ensure the chest tape does not impede mechanical ventilation.

Figure 68.5 Patient positioning in low lithotomy with the full Trendelenburg position for robotic pelvic surgery.

The patient is then prepped and draped from the costal margin to the mid thighs, including the genitalia and perineum. Surgical site preparation and preoperative antibiotic prophylaxis recommendations are the same as for laparoscopic renal surgery with the exception of using povidone–iodine scrub and paint on the genitalia. An LAVH drape is useful for robotic pelvic surgery as it is a combination leg and laparoscopic drape. The field is established such that the bedside assistant can have access to the perineum and genitalia for intraoperative application of perineal pressure during initial anastomotic suture placement and for Foley manipulation. A 20F Foley catheter is placed sterilely on the field and the anesthesia team should place an orogastric tube.

After initial insufflation and port placement, the patient should be placed in a steep Trendelenburg position. The robot is brought in for docking between the

legs. The Allen Yellowfin stirrups should be low enough to accommodate the robot. Once the robot is docked, there should be no additional manipulation of the table position.

Positioning pitfalls

Suboptimal positioning not only can lengthen operative times and lead to surgeon frustration, but can lead to devastating complications. Despite proper patient positioning and preparation, patient injuries have been reported as a consequence of positioning during laparoscopic and robotic surgeries [6, 10]. Wolf *et al*. reported on 1651 procedures that resulted in 46 neuromuscular injuries in 45 patients (2.7%), including abdominal wall neuralgia, extremity sensory deficit, extremity motor deficit, clinical rhabdomyolysis, shoulder contusion, and back spasm. Patients with rhabdomyolysis were more often male, were heavier, and underwent longer procedures. Patients with motor deficits were older. Preexisting nerve dysfunction predisposes patients to motor nerve injury.

It is important for the surgeon to remain comfortable throughout the procedure in order to avoid pain or fatigue. Interestingly, 28% of surgeons in the 18 academic institutions included in Wolf *et al*.'s study reported frequent neck pain and 17% reported frequent shoulder pain [6]. Measures taken by surgeons to alleviate neuromuscular strain included lowering the table maximally, using lifts on the floor, altering the manner in which they held instruments (without fingers through the handles), and altering the position of the monitors.

A devastating complication of robotic pelvic surgery is lower extremity compartment syndrome, which can occur when the patient is placed in Allen Yellofin stirrups in the extreme Trendelenburg position. This complication may require lower extremity fasciotomy [7, 11]. Proper positioning is key to prevention, specifically ensuring the patient's ankle, knee, and contralateral shoulder are aligned in the stirrup, and that gel pads are used directly in contact with the patient's skin to avoid cephalad slippage while in the Trendelenburg position. A high index of clinical suspicion will facilitate early recognition and prompt treatment.

There have been reports of patients developing ischemic optic neuropathy after laparoscopic radical prostatectomy, thought to be a result of a combination of long operative time and the Trendelenburg position [12]. Intraocular pressure measurements in surgical patients confirmed a higher intraocular pressure in patients in the Trendelenburg compared to the supine position [13]. However, the direct clinical consequences of sustained elevated intraoperative intraocular pressures are not known.

Positioning for other robotic procedures

Other robot-assisted laparoscopic pelvic surgery

Positioning for a robot-assisted laparoscopic radical cystectomy and for robot-assisted ureterovesical reimplant is similar to that for robot-assisted laparoscopic radical prostatectomy. The only difference is shifting port placement slightly cephalad to allow for proximal ureteral dissection and for extended bilateral pelvic lymphadenectomy. The 12-mm camera port is placed 2 cm above the umbilicus and the two robotic ports are placed approximately at the level of the inferior border of the umbilicus.

Transperitoneal robot-assisted laparoscopic renal surgery

Positioning for robot-assisted laparoscopic kidney surgery is similar to that for the pure laparoscopic approach. Depending on operating room configuration, the operating table may need to be rotated 90º to accommodate docking the robot. The robot is docked from the ipsilateral side of the table in a direct line between the camera port and the renal hilum.

Conclusions

Time spent properly setting up the operating room and positioning the patient is invaluable. The entire urologic team should be involved in the process with the goal of optimizing outcomes.

Introduction

The use of laparoscopic and robotic techniques in urologic surgery is growing rapidly. Clearly, laparoscopy and robotic surgery provide some important advantages over traditional open techniques, but they also produce new challenges. Patient selection, type of anesthesia, monitoring requirements, and technical challenges created by positioning need to be discussed in advance by the surgeon and anesthesiologist. This chapter reviews the anesthetic and monitoring choices available for laparoscopic surgery and the physiologic changes specific to laparoscopy. The management of pain, nausea, and vomiting are also discussed.

Overview of anesthesia

Anesthetic agents

The choice of anesthetic agents for any surgery depends upon the patient population, duration of surgery, and desire to maintain hemodynamic stability through the surgical stimulus, with an emphasis on minimizing known postoperative side effects, such as pain and postoperative nausea and vomiting (PONV).

Induction of anesthesia

Typical drugs used for induction include sedative hypnotics such as propofol or etomidate. Synthetic narcotics such as fentanyl, remifentanil, or sufentanil are recommended for patients who are unable to tolerate any significant hemodynamic instability during the induction of anesthesia. Depolarizing (succinylcholine) or nondepolarizing (rocuronium, vecuronium) muscle relaxants are also used to ensure an optimal condition for intubation.

Maintenance of anesthesia

Successful maintenance of anesthesia entails a quiescent patient and surgical field, as well as minimal hemodynamic variations associated with pneumoperitoneum or surgical stimulus. The use of inhalational agents, muscle relaxants, narcotics, sedative hypnotics, and antihypertensives, in combination, achieves the goal of balanced anesthesia.

Emergence

The patient's safe emergence and recovery requires full reversal of muscle relaxation. This is typically achieved using a cholinesterase inhibitor such as neostigmine or edrophonium. PONV can be minimized by the use of the selective serotonin 5-hydroxytryptamine 3 (5-HT3) receptor antagonists ondansetron or dexamethasone. Aprepitant, a neurokinin-1 (NK1) receptor antagonist, may be used to alleviate PONV in high-risk patients [1].

Smith's Textbook of Endourology, Third Edition. Edited by Arthur D. Smith, Gopal H. Badlani, Glenn M. Preminger, Louis R. Kavoussi.

Avoiding the use of nitrous oxide has the dual effect of minimizing incidence of PONV as well as optimizing the view of the surgical field by attenuating bowel distention.

Anesthesia techniques

General anesthesia with an endotracheal tube and controlled ventilation is typically used for most laparoscopic procedures, but the use of local anesthesia and regional anesthesia has also been reported.

General anesthesia

General anesthesia with a secured airway and controlled ventilation is considered the safest technique, particularly for cases requiring long periods of sustained pneumoperitoneum. During the insufflation of CO_2, controlled ventilation can be effectively implemented to adjust for increases in end-tidal CO_2 ($PetCO_2$). This is achieved by adjusting the tidal volume and respiratory rate to maintain $PetCO_2$ preferably between 35 and 40 mmHg. The use of a laryngeal mask airway with a spontaneously breathing patient can be considered for cases of shorter duration with relatively low insufflation pressures [2]. Benefits include the avoidance of the use of muscle relaxants and tracheal irritation from intubation. This technique is often seen in the pediatric population in which a transinguinal diagnostic laparoscopy may be used to evaluate the need for surgical intervention on the contralateral side of the known defect.

Local anesthesia

Local anesthesia with sedation can be a viable anesthetic option employed for laparoscopic procedures. The benefits include quicker recovery, decreased incidence of PONV, earlier diagnosis of complications, and fewer hemodynamic changes [3, 4]. The technique is not commonly used, however, as it can also lead to hypoventilation and desaturation secondary to the combined effects of increased intra-abdominal pressure and sedation [5].

Regional anesthesia

Regional spinal or epidural techniques have been developed as an alternative to general anesthesia for surgical procedures using laparoscopy. The benefits include decreased incidence of PONV, decreased postoperative pain, and potentially a shortened course to discharge. Disadvantages include the need for a cooperative patient and shoulder pain associated with pneumoperitoneum-induced diaphragmatic irritation. Careful patient selection, surgeries of short duration, and surgical dissection protocols are necessary when considering the use of regional anesthesia [6–8].

Overview of monitors and invasive lines

Blood pressure, electrocardiogram, heart rate, end-tidal CO_2, temperature, and pulse oximetry must be monitored during laparoscopy. Hemodynamic variations that occur as a result of pneumoperitoneum can be detected and corrected in a timely manner.

The use of invasive monitoring may be considered for patients presenting with concomitant cardiopulmonary disease. Placement of an arterial line can be employed for continuous blood pressure monitoring and the acquisition of blood samples for acid–base and electrolyte analysis. Although this level of monitoring is valuable, it provides only indirect evidence of the hemodynamic changes induced by the pneumoperitoneum. Also, changes in intra-abdominal and intrathoracic pressures can make the use of central venous monitoring unreliable. The use of transesophageal echocardiography can be used to guide fluid management in patients with pre-existing cardiopulmonary disease. Indications for placement of invasive monitors are neither absolute nor all-inclusive. Examples of cases who benefit from the use of an arterial line and/or central line include: when noninvasive monitoring is not possible or unreliable; in patients at significant risk for hemodynamic collapse during induction of anesthesia; in patients with severe cardiopulmonary disease, such as pulmonary hypertension, severe emphysema, or severe cardiomyopathy; in patients with labile blood pressure; in cases where the surgeon and/or anesthesiologist are concerned about blood loss or fluid shifts; in cases who require multiple blood samples; and in cases who will likely need potent vasoactive agents. Additional examples of situations that benefit from the insertion of a central line include patients with little to no peripheral access and patients who will need a central line postoperatively for intravenous alimentation. Alternatively, the routine use of invasive lines is not warranted in healthy patients having laparoscopic surgery by an experienced surgeon when significant blood loss or fluid shifts are not expected. Also, duration of case is not, as a single variable, enough of an indication for use of invasive monitoring lines. Noninvasive blood pressure monitoring and peripheral intravenous access can be used safely for long periods of time in healthy patients undergoing surgery with minimal blood loss or fluid shifts.

In some instances where the indication for an invasive monitoring line is equivocal, the ability to place the line during the case has to be taken into account. For example, if both arms are tucked under the drapes during positioning, providing no access to the arms during the case,

the anesthesiologist may need to lower their threshold for placing an arterial line prior to positioning the patient. Ultimately, the decision to use invasive monitoring lines needs to be made on a case–by-case basis, which is best done by having a preoperative discussion between the anesthesiologist and surgeon.

Laparoscopy and robotic surgery

Physiologic changes caused by insufflation

Pulmonary changes

The effects of instituting pneumoperitoneum on pulmonary physiology is a combination of multiple factors, including mechanical effects, type of gas used to create pneumoperitoneum, patient size, and the existence of any pulmonary pathophysiology with which the patient may present. Diaphragmatic excursion becomes limited as intra-abdominal pressure increases, resulting in decreased lung capacity and compliance with eventual ventilation–perfusion mismatching and shunting [9–11]. Decreases in vital capacity, functional residual capacity, total lung volume, and pulmonary compliance are specifically seen along with increases in peak inspiratory pressures and ventilation–perfusion mismatch [12–14]. The effects of the induction of general anesthesia and pre-existing body habitus can further compound these effects. It is well known that the induction of general anesthesia leads to decreases in the aforementioned lung volumes. Patients who are obese can also present pre-existing atelectasis and decreased lung volumes.

Although CO_2 is the gas most frequently used, other gases such as helium, argon, and nitrous oxide have been used in the past, each with its own benefits and negative consequences on pulmonary physiology. Nitrous oxide is combustible and will diffuse into an air-filled space 34 times faster than nitrogen will diffuse out of that space. Therefore, it is a potential fire hazard and can cause bowel distention, which will diminish surgical exposure. Helium and argon have also been tested in animal models and humans. They are both inert gases and not combustible, but are relatively insoluble and can increase the risk of catastrophic gas emboli [15]. CO_2 has been found to be the safest gas to use in most patients presenting for surgery requiring laparoscopy. It is nonflammable and very soluble, making it easily absorbed into the circulation and eliminated via the lungs. Biochemically, the gas absorption that occurs during insufflation can lead to an imbalance with respect to CO_2 production and elimination. Normal CO_2 production in the average adult is approximately 150–200 mL/min [16, 17]. CO_2 absorption into the systemic circulation via the peritoneum during laparoscopy has been measured at a rate of about 14–48 mL/min [18–21]. As such, adjustments need to be made in minute ventilation, either via increasing tidal volume or respiratory rate, to minimize hypercarbia. If left unchecked, the hypercarbia and resultant respiratory acidosis can lead to depressed cardiac function and arrhythmias. Clinical studies have suggested that subcutaneous emphysema, increased intra-abdominal pressure, extraperitoneal insufflation, and prolonged duration of insufflation can increase the rate of CO_2 absorption.

It is also important to note that not all CO_2 is effectively eliminated during surgery. Some CO_2 can be sequestered, particularly in the skeletal system, and slowly eliminated throughout the postoperative period [22]. This can be of particular concern in patients with pre-existing cardiopulmonary dysfunction, who may not tolerate excessive hypercarbia. Neuberger *et al*. suggested in a study that switching to another gas such as helium after the initiation of pneumoperitoneum would minimize the hypercarbia and may be of some benefit in patients with chronic obstructive pulmonary disease (COPD) or morbid obesity [15]. Clinical studies have suggested that subcutaneous emphysema, increased intra-abdominal pressure, extraperitoneal insufflation, and prolonged duration of insufflation can increase the rate of CO_2 absorption [23].

Cardiac changes

The hemodynamic consequences of pneumoperitoneum and the resultant increased intra-abdominal pressure include a decrease in cardiac output, increase in mean arterial pressures (MAPs), increase in systemic vascular resistance (SVR), and increase in pulmonary vascular resistance. Cardiac output and cardiac index have been reported to initially increase at intra-abdominal pressures less than or equal to 10 mmHg, secondary to increased venous return as a function of autotransfusion. Decrease in cardiac output can be seen as intra-abdominal pressures increase above 20 mmHg [24]. Other factors that affect cardiac output include volume status, patient position, the sympathoadrenal effects of increased intra-abdominal pressures and CO_2 insufflation, and vagal reflexes as a function of peritoneal distention. Hypovolemic patients tend to have a more exaggerated drop in cardiac output in response to increases in intra-abdominal pressure compared to patients who are euvolemic prior to the onset of pneumoperitoneum.

Patients in the Trendelenburg position can exhibit a modest increase in cardiac output. A decrease in cardiac output can conversely be seen in the reverse Trendelenburg position, secondary to decreased venous return. Intra-abdominal pressure decreases venous return secondary to caval compression [25] and increases venous resistance [26, 27]. These observations are

supported by a reduction in left ventricular end-diastolic volume (LVEDV) measured during transesophageal echocardiogram (TEE) [28]. An increase in cardiac filling pressure as a consequence of an increase in intrathoracic pressure is also seen during laparoscopy. As a result, right atrial pressure and pulmonary artery occlusion are unreliable to ascertain cardiac filling pressure [27, 29, 30]. The increases in SVR and MAP are believed to be caused by mechanical and neurohormonal factors [31]. Increases in catecholamine production resulting from surgical stress and increases in intra-abdominal pressure are known to occur. Early stages of hypercarbia also have a sympathomimetic effect, causing the release of catecholamines. As hypercarbia progresses, acidosis becomes more profound and a cardiodepressant effect predominates. The renin–angiotensin system and vasopressin are additionally suspected to contribute to the increase in SVR [29, 32–36].

Renal changes

Oliguria is known to occur during laparoscopic surgery. Urine output in the setting of pneumoperitoneum may not be a reliable indicator of fluid status during laparoscopic surgery. Mistakenly, relying solely on urine output for fluid management may lead to fluid overload.

There are many factors that can cause oliguria, including decreased cardiac output, renal vein compression, ureteral obstruction, renal parenchymal compression, and systemic hormonal effects [37, 38]. Intra-abdominal pressure above 15 mmHg has been shown to consistently cause a decrease in urine output. Miki *et al*. conducted a human study in which low insufflation pressure of 4 mmHg was used along with retraction devices during laparoscopic cholecystectomy [39]. They found that urine output, renal blood flow, and glomerular filtration rate (GFR) remain unchanged [39, 40]. Direct renal parenchymal compression was purported to mimic a Page kidney effect [40]. Razvi *et al*. placed a pressure cuff on canine kidneys, applying pressures of 15 mmHg. They found a decrease in urine output, GFR, and effective renal blood flow [41]. An increase in levels of serum aldosterone, along with an increase in urine potassium and a decrease in urinary sodium, have been reported in animal models [42]. This also supports the theory of the Page kidney effect being a major cause of the intraoperative oliguria seen during laparoscopic procedures.

A decrease in cardiac output has been disproven as a substantial cause of oliguria because normalization of cardiac output with fluid resuscitation does not result in an increase of urine output [37, 38].

Ureteral obstruction is unlikely to cause oliguria because placement of ureteral stents during pneumoperitoneum does not lead to an increase in urine output [43]. Intraoperative urograms have also confirmed the absence of ureteral obstruction during pneumoperitoneum in animals [42].

These intraoperative effects tend to resolve in the postoperative period among healthy patients, but those with pre-existing renal dysfunction may have cause for concern. Cisek *et al*. created an animal model in which renal insufficiency had been simulated via renal reductive surgery [44]. The animals were subjected to prolonged periods of pneumoperitoneum with resultant decreases in urine output, GFR, and renal blood flow despite hydration. Acute renal failure was noted to last 1 week with values returning to the baseline level of renal insufficiency previously created with no long-term impact on renal function [44].

Elevated intra-abdominal pressures may also act to cause oliguria by stimulating increases in endogenous catecholamines. Mikami *et al*. showed that insufflation pressures at or above 20 mmHg resulted in increased catecholamine levels [45]. Endothelin has been shown to increase during pneumoperitoneum and in response to renal vein compression. Compression of a unilateral renal vein leads to a decrease in the GFR and urine output in both kidneys, and is associated with elevated renal vein endothelin concentrations, implicating it as a contributing factor to the oliguria observed during long laparoscopic cases [40, 46]. In animal studies using vasopressin antagonist, renal function improved in comparison to control groups. This implies that vasopressin plays a causal role in the development of oliguria during laparoscopic procedures [47].

Altering the temperature of the insufflant has been shown to partially attenuate the oliguric effects seen with laparoscopic procedures [48]. Backlund *et al*. compared the use of warm (37°C) CO_2 with that of room-temperature CO_2. Higher core temperature, urine output, and cardiac index were observed [48]. This suggests that regional vasodilatation of the renal vasculature may help restore renal blood flow and urine output. The use of warm insufflants to aid in the preservation of urine output may be of benefit to patients with pre-existing cardiac or renal dysfunction by making fluid management more predictable, especially during long cases.

Cerebral blood flow changes

Cerebral hemodynamic variability during laparoscopy can be affected by multiple factors. Cardiovascular changes, alterations in $PaCO_2$, patient position, and raised intra-abdominal and intrathoracic pressures (with or without a rise in $PaCO_2$) can all affect cerebral perfusion dynamics [49]. In an animal study, Rosenthal *et al*. showed significant increases in intracranial pres-

sure at intra-abdominal pressure above 8 mmHg. It is postulated that this is secondary to compression of the large intra-abdominal caval vessels. This leads to an increase in central venous pressures as a result of a decrease in venous drainage from the central nervous system. Placing the patient in the head-down position can also augment this effect.

Cerebral blood flow velocity increases during CO_2 pneumoperitoneum as a result of an increase in $PaCO_2$ [50–52]. Fujii *et al*. studied the effects of intraperitoneal CO_2 insufflation on middle cerebral arterial blood flow velocity in 10 patients during laparoscopic cholecystectomy [51]. A positive correlation between cerebral blood flow velocity and $PaCO_2$ was seen. The hypercapnia associated with CO_2 pneumoperitoneum causes direct cerebral vascular vasodilatation that can lead to increased intracranial pressure. Hyperventilating the patient may attenuate this.

Endocrine response

Many studies have been conducted comparing open and laparoscopic procedures and the stress response associated with each. It has been shown that laparoscopic procedures produce a much lower stress response compared to open procedures. Increases in MAP and SVR are seen during laparoscopy, however. Elevated levels of antidiuretic hormone have been correlated with increases in MAP and SVR during laparoscopic procedures [49]. Furthermore, elevated levels of plasma renin and aldosterone have been correlated with an increase in MAP [35]. Levels of cortisol, human growth hormone, epinephrine, and norepinephrine were found to increase after deflation of pneumoperitoneum. Increases in vasopressin and other endogenous catecholamines such as epinephrine and norepinephrine have been associated with changes in intra-abdominal and intrathoracic pressure [32]. Plasma levels of cortisol and catecholamine are elevated during laparoscopic procedures. Laparoscopy allows for a decrease in acute-phase reactants normally seen during the surgical stimulus. C-reactive protein and interleukin (IL)-6 are significantly lower compared to open procedures [53–55]. The metabolic and inflammatory responses are muted. There is less hyperglycemia and leukocytosis [53, 54].

Effects of common positions during laparoscopy

It is well known that many of the protective reflexes that prevent wide swings or variations in a patient's hemodynamic response to positional changes are blocked or attenuated upon the induction of anesthesia. Some of these reflexes include afferent aortic and carotid baroreceptors, which, under normal circumstances, respond to changes in preload by mediating and modulating sympathetic outflow and vasomotor tone. The result is a well-controlled hemodynamic profile in which blood pressure is maintained and perfusion of vital organs is preserved regardless of position. Changes in position can cause significant hemodynamic compromise during surgery under general anesthesia, however. Changes in pulmonary mechanics are further exacerbated by positional changes under general anesthesia. These pulmonary changes include a decrease in tidal volume, functional residual capacity, and lung compliance, as well as an increase in closing volume, leading to atelectasis and intrapulmonary shunting.

Trendelenburg

Trendelenburg position can increase venous return, central venous pressure, intracranial pressure, and intraocular pressure. It can also improve surgical exposure, but can result in significant cardiopulmonary compromise. A prolonged Trendelenburg position postoperatively may cause soft tissue edema in and around the airway, leading to airway complications. The Trendelenburg position increases the work of breathing in the spontaneously breathing patient, which leads to a decrease in functional residual capacity, tidal volume, and pulmonary compliance. Atelectasis with intrapulmonary shunting may also occur. Controlling tidal volume and respiratory rate under general anesthesia minimizes the aforementioned effects, however.

Reverse Trendelenburg

The reverse Trendelenburg position causes the most significant hemodynamic perturbations when instituted along with pneumoperitoneum [49]. It decreases venous return to the heart, leading to profound hypotension. Concern about cerebral perfusion pressure is warranted. The resultant decrease in blood pressure and MAP can lead to cerebral hypoperfusion. Cerebral perfusion pressure is autoregulated between MAPs of 50 mmHg and 150 mmHg in order to keep tight control on cerebral blood flow under normal circumstances. This protective autoregulatory mechanism is lost when MAPs fall outside of this range, however, and cerebral perfusion becomes entirely flow dependent. Cerebral ischemia may occur during hypotensive episodes. Cerebral hyperperfusion may also occur during hypertensive episodes. This hemodynamic instability may put the patient at risk for cerebrovascular hemorrhagic and ischemic events. Patients with pre-existing abnormal cerebral autoregulatory mechanisms, such as those with chronic hypertension, a history of cerebrovascular accidents, or with carotid occlusive disease, may require higher than normal cerebral perfusion pressures as their autoregulatory curves may be shifted to the right.

Decreased femoral vein flow occurs with CO_2 insufflation and high intra-abdominal pressures, and is exacerbated by the reverse Trendelenburg position [56, 57]. This can increase the risk of deep vein thrombosis (DVT) [58]. The use of intermittent compression devices on the lower extremities can help to reverse the effects of these physiologic changes, thereby minimizing the risk of the development of DVT [58, 59].

Lateral decubitus

The lateral decubitus position is good for procedures requiring retroperitoneal exposure. Care must be taken to keep the head in the neutral position and to avoid pressure on the dependent ear and eye. Stretch or pressure injuries to the brachial plexus can be avoided by the use of an axillary roll placed just below the axilla. It is also prudent to monitor the pulse in the dependent arm via pulse oximetry to detect compression of neurovascular structures. It should also be remembered that this position can lead to ventilation–perfusion mismatch and changes in pulmonary compliance for the dependent lung, as well as overinflation and potential barotrauma to the nondependent lung. A certain amount of flex may be applied to these patients, usually occurring at the iliac crest, in order to maximize exposure. If a kidney rest is used, care must be taken to ensure proper placement at the iliac crest in order to avoid compression of the inferior vena cava.

Lithotomy

The lithotomy position can cause an increase in cardiac output, intracranial pressure, and central venous pressure. It can conversely cause a decrease in lung compliance and tidal volume. The loss of the natural lordotic curvature of the lumbar spine can lead to back pain after prolonged procedures in the lithotomy position. Care must be taken to avoid injury of the common peroneal nerve, the risk of which increases in patients with high body mass index, patients who smoke, and with an increased duration of surgery [60]. Lower extremity compartment syndrome can be seen as a result of decreased perfusion, resulting in ischemia, edema, and rhabdomyolysis. Prolonged surgical time in the lithotomy position can increase the risk of this complication, thus lowering the leg periodically in long procedures can help to prevent this from happening [61–64].

Nerve Injury

There is a risk of nerve injury with any position in which a patient is placed. A review of 81 000 anesthetics performed between 1987 and 1993 showed the incidence of nerve injury to be roughly 0.11% [65]. Ulnar nerve injury has the highest rate at 28%, followed by brachial plexopathy (20%), lumbosacral injury (16%), spinal cord injury (13%), and sciatic nerve injury occurring in 5%, which also includes common peroneal nerve injuries [66]. The American Society of Anesthesiologists Task Force Consensus Findings on Prevention of Perioperative Peripheral Neuropathies showed no clear etiology for ulnar neuropathies and concluded that the cause was multifactorial [67]. It suggested that, when tucked, the upper extremities should be appropriately padded in the neutral position with the palms toward the body. If the upper extremities are abducted, they should be kept in the supinated or neutral position with the palms toward the body [67]. Brachial plexus injuries occur as a result of stretching if the arms are abducted greater than 90° from the body for a prolonged period of time or compression, as can be seen in the lateral decubitus position. The use of an axillary roll is customarily employed to minimize the risk of this complication. Injuries to the sciatic nerve and common peroneal nerve commonly occur in the lithotomy position. Stretching of the nerve by excessive or prolonged external rotation of the leg, hyperflexion of the hips, or extension of the knee is the most frequent cause of sciatic nerve injury. Common peroneal nerve injuries are mostly due to compression of the nerve between the fibular head and the leg support frame.

Specific anesthetic considerations

Fluid management

Compared to open procedures, laparoscopic procedures tend to cause less fluid shifts and insensible losses. There is a decrease in urine output at intra-abdominal pressures greater than 10–15 mmHg, which can predispose patients to fluid overload during long laparoscopic procedures. Intraoperatively, it is advisable not to rely solely on urine output for fluid management. Volume status should be optimized prior to insufflation, if possible. For fluid replacement during the procedure, maintenance of fluid in the range of 5 mL/kg/h plus appropriate replacement for blood loss is considered a good method for fluid resuscitation without causing fluid overload [24, 68].

Gas embolism

Gas embolism, although rare, is usually seen immediately after insufflation and is caused by gas bubbles entering the systemic circulation and causing cardiovascular collapse. Symptoms include hypoxemia, hypercarbia, decreased cardiac output, pulmonary edema, increased airway pressures, hypotension, jugular venous distention, and dysrhythmias. Arterial

embolization through a patent foramen ovale may occur if right heart pressures exceed left heart pressures. The incidence of venous gas embolism (VGE) has been estimated to be between 0.002% and 0.08% [24], although clinically detectable VGE may occur in as many as 0.59% of laparoscopic cases when careful surveillance is used [30]. A characteristic millwheel murmur can be auscultated. Widening of the QRS complex with a right heart strain pattern on electrocardiography (ECG) can also be seen.

Successful treatment requires quick intervention, including desufflation, ventilation with 100% FIO_2, steep head-down tilt with the right side up, and other supportive measures. Outcomes depend on the type of gas used. Air, which is 80% nitrogen, is resorbed very slowly in blood. CO_2 is 47 times more soluble than nitrogen. Graff *et al*. found the LD50 of CO_2 to be five times that of air when injected intravenously in dogs [69]. Helium as an alternative to CO_2 is even less soluble than nitrogen, however. Intravenous injection of helium (5–10 mL/kg) was lethal on four of six occasions in canine experiments, while the same amount of CO_2 was followed by hemodynamic recovery within 2 min in all cases [70]. Argon VGE during laparoscopic use of an argon beam coagulator has been reported. Helium and argon should therefore not be used for initial insufflation, but their use is possible in order to avoid hypercapnia after pneumoperitoneum via CO_2.

Subcutaneous emphysema

Subcutaneous emphysema occurs when gas leaks into extraperitoneal tissue planes. Etiologies include incorrect insufflation needle placement, excessive intra-abdominal pressures, malfunctioning equipment, or leaks around a laparoscopic port placed with an open technique. Extraperitoneal gas leads to increased gas absorption, which can manifest in the subcutaneous compartment as well as the thoracic cavity. Pneumomediastinum, pneumothorax, and pneumopericardium can inhibit cardiac filling and limit lung excursion.

Logistic considerations in urologic robotic surgery

The use of robotics in urologic surgery first began in the late 1980s when a robotic frame was developed for transurethral resection of the prostate [71]. There have been improvements made by several different companies over time with respect to complexity of the system. The da Vinci Robotic Surgical System is currently the primary system used. Procedures that use the da Vinci systems include radical prostatectomy, radical cystectomy, radical and simple nephrectomy, live donor nephrectomy, pyeloplasty, and adrenalectomy [71].

There are concerns specific to laparoscopic robotic surgery that should also be borne in mind. The patient's proximity to the robotic apparatus makes access to the upper extremities particularly challenging. Appropriate venous access should be obtained prior to the patient's final positioning. After careful consideration of the type of surgery, operative time, and experience of both surgeon and anesthesiologist, invasive monitoring such as an arterial line or a central venous pressure line may be placed prior to positioning the patient (see above).

Once in position and the patient is prepped and draped, surgery commences and instruments are connected to the robotic arms. It is imperative that the patient does not move once the instruments are inside them. Any movement can cause trauma to the patient. An intermediate- or long-acting nondepolarizing muscle relaxant such as vecuronium or pancuronium should be utilized to maintain adequate muscle relaxation throughout the case.

Careful attention should be paid to positioning, particularly during long cases. Positions such as Trendelenburg and low lithotomy carry increased risk for brachial plexus and lower extremity nerve injury (see above). The Trendelenburg position along with high intra-abdominal pressures for greater than 4 h can lead to airway edema. This should be kept in mind during the emergence and extubation period. Ensuring that there is an appropriate leak around the deflated endotracheal tube cuff and checking for any significant degree of scleral edema may help guide the decision process to extubate the patient immediately after surgery or not. Other considerations to guide this decision include concerns regarding fluid status, acid–base abnormalities, hypothermia, or general unexplained hemodynamic instability. As previously mentioned, fluid management should be carefully assessed and judiciously administered during long laparoscopic procedures, such as when robotic techniques are employed. Being mindful of the effects of pneumoperitoneum, positional changes, perioperative fluid status, preexisting renal disease, and temperature on urine output can help to avoid fluid overloading these patients.

Hypothermia during these cases can cause many problems in addition to possible oliguria. Coagulation defects and wound infection are also two well-known side effects associated with mild hypothermia [72, 73]. Postoperative alopecia after long surgical cases under anesthesia is also a risk. Ischemia to the hair follicles secondary to hypothermia or hypoperfusion is a causative factor [74].

To minimize prolonged periods of pressure at any one point of the head, care must be taken to pad and protect the occipital region and to rotate the head periodically. Back pain associated with long surgical times in the supine or lithotomy position have been documented

and is suspected to be secondary to loss of the normal lordotic curve and decreased tone of the paraspinous muscles [74].

Anesthesia for high-risk patients

The value of laparoscopic procedures has increased over the last decade. This has become particularly apparent in urology. Advances in this area now routinely include laparoscopic varicocelectomy, hernia repair, adrenalectomy, partial adrenalectomy, renal pelvis or ureter percutaneous stone retrieval, radical prostatectomy, extra-adrenal pheochromocytoma, nephropexy, pyeloplasty, nephrectomy, partial nephrectomy, and cystectomy. Considerable advances in robotic technology have also yielded important tools for performing some of these surgeries.

Many patients undergoing minimally invasive urologic laparoscopic surgery have coexisting diseases. As a result, progressively older patients with corresponding pulmonary, renal, and cardiovascular comorbidities, as well as morbidly obese and pregnant patients, are now undergoing advanced laparoscopic surgery. Detailed knowledge of the respiratory and hemodynamic pathophysiology induced by CO_2 pneumoperitoneum and extremes of patient positioning is necessary to administer safe anesthesia to such patients.

Cardiac patients

Significant hemodynamic changes during pneumoperitoneum raise the question of tolerance of these changes among cardiac patients. Patients with cardiac disease are at an increased risk of developing myocardial ischemia during laparoscopy due to increase in myocardial wall tension caused by increased MAP and SVR [75]. Risk for myocardial ischemia may be exacerbated by insufficient tissue oxygen delivery manifested by a reduction in mixed venous oxygen saturation caused by a decreased cardiac index [75]. Preoperative evaluation may include echocardiography. Patients with severe congestive heart failure and terminal valvular insufficiency are more prone to develop cardiac complications than patients with ischemic cardiac disease during laparoscopy [50]. Intraoperatively, arterial blood pressure, heart rate, ECG, capnometry, and pulse oximetry must be continuously monitored. Pulmonary artery catheterization may be additionally useful in monitoring mixed venous oxygen saturation and cardiac index. TEE may be necessary to assess regional wall motion abnormalities, filling volumes, and ejection fractions [76]. Preload augmentation prior to pneumoperitoneum may be necessary. The magnitude of decrease in cardiac index is directly related to insufflation pressure [76]. Slow and gradual abdominal insufflation to a maximum pressure of 10 mmHg followed by a limited 10° head-up tilt has been associated with cardiovascular stability [77]. Hemodynamic monitoring should be continued in the postanesthesia care unit (PACU). The hyperdynamic state developing after laparoscopy could conceivably lead to a precarious hemodynamic situation in patients with cardiac disease. Increased oxygen demand is also observed after laparoscopy. Therefore, oxygen should be administered postoperatively, even to healthy patients [78].

Patients with pulmonary dysfunction

Considerable CO_2 absorption can occur during laparoscopic surgery (see above). The absorbed CO_2 can have deleterious effects in patients with pre-existing pulmonary dysfunction. Reduced compliance also impedes adequate pulmonary gas exchange and may predispose a patient to pneumothorax and pneumomediastinum [12, 79, 80]. Preoperative pulmonary function testing should be performed, including arterial blood gas analysis. Under normal circumstances, end-tidal CO_2 can be used to estimate the $PaCO_2$. The correlation between end-tidal CO_2 and $PaCO_2$ during laparoscopic procedures may be poor because of a reduced cardiac index and increased ventilation–perfusion mismatch. As such, intraoperative measurement of inspiratory plateau pressure and serial $PaCO_2$ are recommended. If refractory hypoxemia, hypercapnia, or high airway pressures occur, the pneumoperitoneum should be released, followed by slow reinsufflation to achieve lower intra-abdominal pressures. Addition of 10 cmH_2O of positive end-expiratory pressure (PEEP) has been shown to attenuate the effects of pneumoperitoneum in respiratory mechanics [81]. Conversion to an open procedure must be considered if complications persist. Helium may be used as an alternative insufflant, which may prevent respiratory acidosis and hypercapnia associated with CO_2 pneumoperitoneum. Gasless or apneumic laparoscopy can similarly be used as an alternative to avoid the potential side effects of CO_2 pneumoperitoneum. Despite these problems in patients with respiratory disease, laparoscopy remains preferable to laparotomy because of reduced postoperative respiratory dysfunction.

Renal patients

Renal function and renal blood flow are decreased during pneumoperitoneum. The magnitude of the decrease is dependent on factors such as preoperative renal function, level of hydration, duration of pneumoperitoneum, level of pneumoperitoneum, and patient positioning. Increased intra-abdominal pressure can reduce urine output. Assuming a euvolemic status,

intraoperative management for oliguria should include evaluation of the Foley catheter for patency and laparoscopic examination of the bladder. Anuria may develop in patients with pre-existing renal dysfunction. The role of dopamine to enhance intraoperative urine output is unclear. Infusion of low doses of dopamine during laparoscopic colectomy had higher urine output compared with patients who did not receive dopamine [82]. Infusion of low-dose nicardipine during robot-assisted laparoscopic radical prostatectomy has also been shown to offset the effects of pneumoperitoneum and extreme head-down tilt on renal function [83]. As a corollary, a management strategy to avoid hypovolemia and preserve renal perfusion pressure has been shown to preserve renal function in both the donated and remaining kidneys during laparoscopic kidney donation [84]. It appears that excessive fluid administration is not necessary to preserve renal function, assuming the absence of hemorrhage and use of a low level of intra-abdominal pressure. A host of neurohormonal changes also occur, resulting in increases in aldosterone, renin, and antidiuretic hormone [85, 86]. These changes may be exaggerated in patients with pre-existing renal dysfunction, but they are not permanent [85]. Renal function and electrolytes return to baseline within a variable time after pneumoperitoneum is released [87, 88]. Although renal function and renal blood flow do not appear to be clinically deleterious, knowledge of the effects of insufflation is important to effectively monitor and maintain an appropriate fluid balance for patients during laparoscopy.

Pregnant patients

Laparoscopic surgery during pregnancy presents several concerns, including increased risk of miscarriage or premature labor, increased risk of damaging the gravid uterus, and significant fetal acidosis. Abdominal and pelvic procedures are associated with the greatest incidence of premature labor. Procedures are best scheduled in the mid trimester, decreasing the risk of teratogenic effects of some medications (first trimester) or preterm labor (third trimester). Laparoscopic surgery is considered safe during pregnancy, however [89]: laparoscopy carried out between 4 and 32 weeks of gestation have resulted in uncomplicated pregnancies [90–94]. On hemodynamics and breathing, when compared to nonpregnant patients, pneumoperitoneum does not induce any additional effect. CO_2 pneumoperitoneum nonetheless can cause significant fetal effects, including increased heart rate, increased arterial pressure, and increased blood pH [95]. Interestingly, fetal outcomes are similar with either laparotomy or laparoscopy [96]. For monitoring, preoperative and postoperative fetal heart rate and uterine activity must be assessed at a minimum. Fetal monitoring may be performed using transvaginal ultrasonography [90]. Capnography may be adequate to guide maternal ventilation. As long as physiologic maternal alkalosis is achieved, uteroplacental blood flow should be maintained. Essentially, fetal perfusion pressure and blood gas values should remain at normal levels [97]. Left uterine displacement should be used after 20 weeks of gestation and aspiration prophylaxis administered to all pregnant patients. Other technical considerations should include fetal shielding, pneumatic stockings, and open trocar placement [98].

Obese patients

Obesity is complex and multifactorial, and is defined as a condition of excessive fat accumulation in adipose tissue to the extent that health deteriorates and life-expectancy is shortened. Given the comorbidities associated with obesity, it is surprising to find a paucity of literature revealing a definitive increase in overall operative risk. The widespread introduction of laparoscopic gastric bypass has significantly augmented the experience with laparoscopy in morbidly obese patients. Laparoscopy has many advantages, including less postoperative pain, earlier recovery, and reduced risk of pulmonary complications.

Preoperative investigation should be directed by history and examination findings of the patient. Spirometry as a preassessment screening tool does not make any difference in predicting postoperative pulmonary complication [99]. A careful preoperative assessment of a patient's upper airway is always required because mask ventilation and tracheal intubation can be a challenge. Patients using nasal continuous positive airway pressure and bi-level-positive airway pressure should be instructed to bring them to the hospital to use in the PACU after surgery. A preoperative discussion about the need for extubation when fully awake and in a sitting position may minimize patient anxiety and improve cooperation during recovery.

Basic intraoperative monitoring should include $PetCO_2$, urine output, and $PaCO_2$ levels. Certain obese patients, particularly those with evidence of pulmonary hypertension and cor pulmonale, may benefit from invasive cardiovascular monitoring, including Swan–Ganz catheterization and radial arterial catheter with routine blood gas measurement.

Atelectasis can be a significant clinical problem in the perioperative period because functional residual capacity and pulmonary compliance are reduced in obese patients [100]. Concurrently, pneumoperitoneum worsens compliance and functional residual capacity, requiring modification of ventilatory parameters.

Endotracheal tube position must be carefully monitored because both the head-down position and

abdominal insufflation can cause migration of the endotracheal tube into the right mainstem bronchus [101].

Hypoxemia during mechanical ventilation in obese patients, at least, is due in part to ventilation–perfusion mismatch [102]. PEEP has been shown to provide an improvement in ventilation–perfusion mismatching and arterial oxygenation in morbidly obese patients through alveolar recruitment [103], but adverse effects on cardiac output and oxygen delivery may offset these benefits. Patients with obstructive sleep apnea and obesity hypoventilation syndrome should be closely monitored and supplemental oxygen should be provided in the immediate postoperative period. The maximum decrease in PaO_2 usually occurs 2–3 days postoperatively. Depression of ventilation in obese patients is a concern. As part of a multimodal approach, opioids and adjuvant analgesics comprise an effective method for producing postoperative analgesia.

The likelihood of DVT and pulmonary embolism is also increased, emphasizing the importance of physiotherapy and the need for prophylactic anticoagulation. Since the risk of pressure ulcers and subsequent wound infection is high, meticulous attention to pressure points is essential. Rhabdomyolysis, potentially a fatal complication associated with prolonged surgery in obese patients, may be associated with gluteal muscle necrosis [104, 105]. As such, preventive measures should include meticulous intraoperative positioning, suitable intraoperative padding, and limiting the duration of the operation. Serial creatine phosphokinase (CPK) measurement is essential. Critical CPK level may be treated aggressively with hydration and diuresis to prevent renal failure.

Despite these potential pitfalls, laparoscopy is usually well tolerated in obese patients and many studies show reductions in overall morbidity when a laparoscopic technique is used [106, 107].

Postoperative pain

Laparoscopy has been shown to reduce postoperative pain and analgesic consumption [108]. Improving postoperative analgesia in laparoscopic surgery remains an area of continued interest.

The nature of pain includes visceral pain, parietal pain resulting from peritoneal inflammation and tissue manipulation at the trocar or hand-assist site, and shoulder-tip pain resulting from diaphragmatic irritation [108, 109]. The mainstay of pain prevention and treatment relies on local anesthesia, nonsteroidal anti-inflammatory drugs (NSAIDs), and opioids [110–112]. Dexamethasone is also an effective adjuvant in reducing postoperative pain [113]. Residual pneumoperitoneum gas has been shown to contribute to postoperative pain [111, 114]. Surgeons are encouraged to desufflate the pneumoperitoneum gas to the greatest extent possible at the conclusion of the procedure.

Multimodal analgesia is now recommended due to the multifactorial etiology of pain after laparoscopy. The pharmacologic underpinnings of this technique involve attacking pain signaling at different sites (Table 69.1). The goal is to reduce the total dose of any one medication by attending to patient analgesic requirements through various receptor modulations. Employing this technique minimizes the need for high doses of opioids and their accompanying toxicity. It may decrease the patient dependence on opioids for acute postoperative pain control.

Opioids are effective in treating pain after laparoscopic procedures, but these medications are not without adverse effects. Numerous side effects include nausea and vomiting, constipation, ileus, confusion, sedation, urinary retention, delirium, pruritus, headache, respiratory depression, and potentially more serious effects, including muscle rigidity and hypotension. Paradoxically, opioids can cause hyperalgesia [115–117].

Acetaminophen has been shown to decrease opioid requirements by 25–35% [118]. It has minimal effect on platelets and gastric mucosa, and does not trigger asthma in susceptible patients. Acetaminophen is hepatotoxic at dosages exceeding 4 g/day, so its use should be monitored in patients with liver disease and in patients receiving hepatotoxic medications.

NSAIDs are often administered as adjuvant during and after surgery. They have analgesic properties comparable with opioids, but do not have opioid-related side effects. There seems to be no significant differences among various NSAIDs in analgesic efficacy. Following surgery, patients treated with preoperative NSAIDs consume 25–33% fewer opioids and report lower pain scores [119]. Caution should be exercised, however, in prescribing NSAIDs to patients with pre-existing renal dysfunction [119, 120], asthma or nasal polyps, ulcers or gastrointestinal bleeding. NSAIDs may cause fluid retention in the elderly and may be associated with impaired bone healing in orthopedic surgical patients [121].

The gabapentinoid group of drugs, gabapentin and pregabalin, have recently gained favor in the treatment of acute postoperative pain. They have been shown to decrease pain, opioid consumption, and opioid-related side effects postoperatively [122, 123]. A randomized, placebo-controlled, double-blind study in healthy volunteers showed that gabapentin enhanced the analgesic effect of morphine [124]. These adjuvant agents have potential, but more work is required to determine the optimal dosing and duration of use.

NMDA receptor antagonists are a mainstay in the treatment of opioid-tolerant and hyperalgesic patients.

Table 69.1 Commonly used analgesics for laparoscopic surgery.

Analgesics	Sites of action
Opioids	Peripheral: reduced calcium entry into nociceptive afferents Spinal cord: hyperpolarization of dorsal horn neurons Supraspinal: enhanced efferent inhibitory neuron activity
Acetaminophen	Peripheral: suppresses peripheral PGE2 release and interleukin formation CNS: binds cannabinoid-1 receptor
NSAIDs	COX inhibition with decreased PGE2 centrally and peripherally
Gabapentinoids	Brainstem: enhanced descending inhibitory pathways Spinal and afferent peripheral nerves: $\alpha 2$ subunits of calcium channels
Ketamine	Inhibits glutamate binding of NMDA receptors in dorsal horn of spinal cord
Dexmedetomidine, clonidine	Supraspinal: $\alpha 2$ adrenoreceptors in locus ceruleus Spinal: $\alpha 2$ adrenoreceptors in the dorsal horn
Glucocorticoids	Decreases central and peripheral inflammatory mediators
Local anesthetics	Peripheral: decreased interleukin release Central: inhibition of dorsal root ganglion and frequency-dependent conduction

PGE2, prostaglandin E2; NSAID, nonsteroidal anti-inflammatory drug; COX, cyclo-oxygenase; CNS, central nervous system.

Ketamine, the prototypical NMDA receptor antagonist, has undergone a dramatic renaissance in clinical use. Subanesthetic dosages of 10–15 mg given just before surgical incision seem to diminish pain for several days and are not associated with the significant adverse effects related to ketamine administration [125, 126]. A Cochrane Review concluded that subanesthetic ketamine dosing effectively reduces morphine requirements in the first 24 h after surgery, as well as PONV [127].

The alpha2-adrenergic agonists, clonidine and dexmedetomidine (DEX), have significant anesthetic and analgesic-sparing effects. Intravenous perioperative DEX infusion during abdominal surgery has been shown to provide postoperative analgesia and reduce postoperative morphine requirements without clinically relevant bradycardia or hypotension, oversedation, or respiratory depression [128–130]. In a study involving morbidly obese patients, DEX infusion (0.5–0.7 μg/kg/h), instituted 1 h before the end of surgery and continued in the PACU stay, was associated with lower opioid requirements, better pain control, and was not associated with respiratory depression [131].

Glucocorticoids act on diverse targets to control inflammatory, metabolic, hormonal, and immune responses to surgery. The benefits of corticosteroids may be maximized by repeated dosages. The fear of adverse effects (such as adrenal suppression, wound healing, or gastrointestinal ulceration) likely hinders their widespread clinical use, despite modest analgesic actions [113].

Local anesthetics have a variety of applications in perioperative pain management. Local anesthetic infiltration (e.g. intraperitoneal, port-site infiltration) for postoperative pain relief after laparoscopic surgery produces mixed results [132–137]. Although there was some initial enthusiasm that protracted analgesia would result from surgical-site local anesthetic infiltration, the preponderance of evidence does not support this concept.

In summary, postoperative pain remains a major reason for delayed discharge, unplanned admission, and patient dissatisfaction. The management of acute postoperative pain is complex. Recent advances in our understanding have improved our approach to postoperative pain management, but there is a paucity of randomized clinical trial data to provide definitive, high-quality, evidence-based recommendations. Selected nonopioid analgesics can be used as part of a multimodal approach for optimizing acute pain management. Further studies are needed, however, to determine the optimal dosing and duration of use, as well as the patient population that would benefit from these adjuvant analgesics. The use of the multimodal approach to analgesia will continue to advance, further improving patients' long-term outcomes and levels of satisfaction.

Postoperative nausea and vomiting

Despite widespread use of antiemetics for preventing and treating PONV, many surgical patients who undergo general anesthesia still experience PONV in the PACU, the hospital, and at home after discharge [138, 139]. PONV can increase medical costs from delayed recovery room discharge or unplanned admissions after outpatient surgery [140]. Additionally, nausea and vomiting are among the most unpleasant experiences associated with surgery for many patients and one of the most common reasons for poor patient satisfaction in the postoperative period [141]. PONV may be associated with wound dehiscence, pulmonary aspiration, electrolyte disturbance, dehydration, Mallory–Weiss tear, loss of vision, and subcutaneous emphysema [142–144].

The etiology of PONV is multifactorial. Patient-related risk factors for PONV include female gender, nonsmoking status, anxiety, age 3–14 years, history of PONV, and motion sickness or migraines [144–149]. Surgery-related factors include increasing duration of surgery [149, 150] and certain types of surgery, although causality has not been clearly established (with the exception of strabismus surgery in children) [146]. Anesthesia-related factors include use of volatile agents [150], nitrous oxide [151, 152], opioids [145, 153], and large doses of neostigmine [154] for reversal of neuromuscular blockade.

Simplified scoring systems developed by Apfel *et al.* [145] and Eberhart *et al.* [155] to identify patients at risk for PONV have been shown to significantly reduce the overall incidence of PONV. The Apfel score, which was developed for adults, consists of four predictors: female gender, history of motion sickness or PONV, nonsmoking status, and the use of opioids for postoperative analgesia. The Eberhart score, which was developed for children, similarly consists of four predictors: duration of surgery of 30 min or longer, age 3 years or older, strabismus surgery, and history of POV in the child or POV/PONV in a parent or sibling.

The pathogenesis of PONV involves several receptor systems, including dopaminergic D2 receptors, cholinergic muscarinic receptors, histaminergic H1 receptors, serotonin 5-HT3 receptors, and NK1 receptors. Antagonists to these receptors are the mainstay of PONV management.

The most commonly used dopamine receptor antagonists are metoclopramide and droperidol. Droperidol at a dose of 0.625–1.25 mg has been demonstrated to be highly effective for the prophylaxis of PONV [156]. Concerns regarding prolongation of QTc interval led to the issuance of a black box warning by the US Food and Drug Administration (FDA) in December 2001. It appears, however, that QTc prolongation is dose dependent. When given at doses less than 2.5 mg, this prolongation is modest and transient [157]. The use of this antiemetic continues to decline. Haloperidol at a dose of 1–2 mg may be a suitable alternative, but data regarding safety and efficacy are lacking [158, 159]. Metoclopramide in doses of 25 mg and 50 mg was similarly effective for PONV prophylaxis [160]. The commonly used dose of 10 mg seems to be no more effective than placebo [161, 162]. Promethazine is also an effective antiemetic [163], but its use is limited by sedation and prolonged recovery from anesthesia [162]. Promethazine also has a black box warning regarding the risk of respiratory depression in children younger than 2 years [164].

The most widely used anticholinergic for PONV prophylaxis is transdermal scopolamine (TDS). It is effective in the setting of outpatient laparoscopy [165]. Common side effects, including dry mouth, visual disturbances, dizziness, and agitation, limit its use, however [166]. Antihistamines, including diphenhydramine and dimenhydrinate, seem to be similarly effective for PONV prophylaxis, but their use is limited due to side effects such as sedation, dry mouth, blurred vision, urinary retention, and delayed recovery room discharge [167].

Serotonin receptor antagonists are highly specific and selective for nausea and vomiting. First-generation 5-HT3 receptor antagonists include ondansetron, granisetron, dolasetron, and tropisetron. New-generation 5-HT3 receptor antagonists approved by the FDA include palonosetron. There seems to be no evidence that there is any difference in efficacy and side effect profile among the various 5-HT3 receptor antagonists, but first-generation 5-HT3 receptor antagonists are extensively metabolized. As a result, ultrarapid metabolizers have an increased incidence of therapeutic failures [167–169].

Palonosetron, on the other hand, has a 30-fold greater binding affinity [170] for the receptor than other antagonists and a substantially longer half-life [171]. These unique characteristics may confer advantages when used in the treatment of established PONV, but further investigations are needed.

Aprepitant is the only NK1 receptor antagonist currently available for management of PONV in the USA [1]. It has a long duration of action and a favorable side effect profile. It seems to be effective for prophylaxis against vomiting.

Other antiemetic interventions include dexamethasone [151], which is most effective when given at induction of anesthesia [172], total intravenous anesthesia with propofol [173], and aggressive intravenous hydration [174]. Other strategies to keep the baseline risk of PONV low are avoidance of emetogenic stimuli (nitrous oxide [175], inhalational agents [176], minimal use of intraoperative and postoperative opioids, judicious use

of neostigmine [154], and nonpharmacologic techniques, e.g. acupuncture [177]).

Due to the multifactorial etiology of PONV, a panel of experts recommends a multimodal approach to managing patients at moderate-to-high risk for PONV [24] and, according to the issued guideline, a risk-adapted strategy should be adopted for PONV prophylaxis. Strategies to reduce baseline risk for PONV should also be employed. For the treatment of established PONV, an agent from a pharmacologic class different from the agent used for prophylaxis should be used. If no prophylaxis was used, administration with a low-dose 5-HT3 receptor antagonist is recommended.

In summary, improved understanding of the risk factors for PONV and effective patient communication may help establish the level of risk, determine the need for preventive measures, and implement rescue treatment immediately by targeting mechanisms that have not been tried before.

Conclusions

General endotracheal anesthesia is the best choice for most cases of laparoscopic and robotic urologic surgery. In specific circumstances, alternatives such as the use of a laryngeal mask airway, regional anesthesia, and local anesthesia can be considered. The choice of anesthesia and monitoring are mostly dependent on expected surgical challenges and patient comorbidities. Both the surgeon and the anesthesiologist need to be aware of the physiologic effects of laparoscopy when selecting patients for this form of surgery. Most patients tolerate anesthesia for laparoscopic surgery safely but an occasional patient will be challenged by the cardiac and pulmonary effects of positioning and insufflation. These issues need to be discussed prior to the induction of anesthesia. To aid in the communication between surgeon, anesthesiologist, and operating room nurse, many health care institutions have adopted the World Health Organization (WHO) surgical safety checklist, which has built-in communication protocols, prior to induction of anesthesia, prior to incision, and during closure of surgery. In a multinational study by Gawande *et al*., the use of the WHO surgical safety checklist reduced postoperative morbidity and mortality by 36% [178].

CHAPTER 70

Pneumoperitoneum: Physiologic Effects

Jay D. Raman[1] & Jeffrey A. Cadeddu[2]

Introduction

In its infancy, laparoscopy was largely employed as a diagnostic tool with limited therapeutic applications such as tubal ablation [1]. As such, these procedures were typically short in duration, associated with minimal morbidity, and most commonly performed in healthy, young females. With the introduction of the laparoscopic cholecystectomy in 1990 and nephrectomy in 1991, the removal of larger solid organs became feasible and laparoscopy evolved from the realm of diagnostic to therapeutic procedures [2, 3]. Since that time, the skill and instrumentation of the laparoscopic surgeon has significantly expanded, which in turn has increased the complexity and duration of these procedures. Modern day laparoscopic and robotic surgeries address a broad spectrum of pathologic conditions in patients with varied states of health. As a consequence, the impact of prolonged pneumoperitoneum has become a central issue for these patients both during and following surgical procedures. This chapter addresses the physiologic effects of pneumoperitoneum and the potential complications arising from it.

Insufflation agents

Early in the evolution of laparoscopy, pneumoperitoneum was established using either room air or oxygen [4]. However, the potential for significant adverse sequelae relating to venous air embolism, intra-abdominal explosion, and combustion with oxygen and room air soon terminated their roles in a clinical setting. The consensus among laparoscopic surgeons was that the ideal insufflation agent should be readily available, inexpensive, noncombustible in nature, and rapidly soluble in plasma [5]. With such criteria, the most commonly employed gas for insufflation is CO_2. The rapid absorption of CO_2 minimizes the likelihood of postoperative abdominal distention and directly contributes to the low probability of developing an air embolus. Nonetheless, its favorable absorption characteristics can precipitate a series of more significant physiologic sequelae, including hypercapnia, hypercarbia, or cardiac dyssrythmias. Such considerations are typically self-limiting, except for patients with depressed cardiopulmonary function or those with chronic obstructive pulmonary disease (COPD). These latter patients in particular may be unable to increase minute ventilation sufficiently to adequately compensate for increased CO_2 absorption.

Alternative insufflation agents have included NO_2 and helium. In the 1970s and 1980s, NO_2 emerged as a favorite insufflation agent with cited benefits including lower cost, less peritoneal irritation, and fewer cardiovascular adverse effects when compared to CO_2 [6, 7]. However, unlike CO_2, NO_2fails to suppress combustion and case reports of intraoperative explosion have limited its therapeutic use [8, 9]. As such, NO_2 can only be used during laparoscopic procedures that do not require the use of electrosurgical equipment. Helium, in contrast, is an inert and noncombustible insufflant, with several studies in animal models demonstrating favorable effects on arterial partial pressure without evidence of

Smith's Textbook of Endourology, Third Edition. Edited by Arthur D. Smith, Gopal H. Badlani, Glenn M. Preminger, Louis R. Kavoussi.

hypercarbia or acidosis [10]. Clinical experience has further supported the use of helium in select patients with pulmonary disease in whom hypercarbia would be poorly tolaterated [11]. The principal drawback of helium is its lower blood solubility, which may be associated with a higher risk of gas embolism.

The focus of this chapter will be on sequelae of pneumoperitoneum, specifically as they relate to CO_2 insufflation, because this is the most commonly used agent during laparoscopic procedures. Generally speaking, physiologic effects of pneumoperitoneum are attributable to two independent variables: (1) increased intra-abdominal pressure; and (2) absorption of the gaseous medium used for insufflation.

Pressure-related effects

Cardiovascular effects

The cardiovascular impact of increased intra-abdominal pressure relates to changes in cardiac function and venous return (Table 70.1). Animal studies suggest that elevated intra-abdominal pressure contributes to an increase in peripheral vascular resistance, which negatively influences cardiac function (12–14). The effect of increased intra-abdominal pressure on venous return is determined by changes in venous resistance and mean systemic pressure. At low right atrial pressures, increased intra-abdominal pressure causes compression of the inferior vena cava (IVC), which inhibits venous return. In contrast, at high right atrial pressures, the IVC resists compression and venous return is augmented by increased intra-abdominal pressure [12–15]. Additionally, increased intra-abdominal pressure mediates compression of small capacitance vessels, thereby augmenting venous return and increasing mean systemic presssure.

Table 70.1 Cardiovascular and renal effects of increased intra-abdominal pressure (10–20 mmHg).

Parameter	Change
Cardiovascular	
Heart rate	↔ or ↑
Mean arterial pressure	↑
Systemic vascular resistance	↑
Venous return	↓
Central venous pressure	↑
Cardiac output/index	↔ or ↓
Stroke volume	↓
Renal	
Renal blood flow	↓
Glomerular filtration rate	↓
Urine output	↓
Serum creatinine	↔ or ↑
Vasopressin (ADH)	↑

Clinically, the degree to which various cardiovascular parameters change during surgery relates to several factors, including intra-abdominal pressure, patient position, CO_2 absorption, intravascular volume status, pre-existing cardiopulmonary status, and current medications. Pneumoperitoneum appears to uniformly induce phasic hemodynamic changes that are initially characterized by a decrease in cardiac index by approximately 50% within 5 min of insufflation, followed by a gradual increase in cardiac index as systemic vascular resistance (SVR) drops after 10 min of insufflation [16]. McLaughlin *et al*. demonstrated that an intra-abdominal pressure of 15 mmHg resulted in a 30% decrease in cardiac output and stroke volume, and a 60% increase in mean arterial pressure (MAP) [17]. Dexter *et al*. further randomized 20 laparoscopic cholecystectomy patients to either low (7 mmHg) or high (15 mmHg) pressure pneumoperitoneum. Although heart rate and MAP increased to a similar degree in both groups, stroke volume and cardiac output were depressed to a greater extent in the 15 mmHg group [18].

Changes in patient position can also alter hemodynamic function. In particular, patients are often placed in a Trendelenberg or reverse Trendelenberg position to facilitate visualization during laparoscopy. Joris *et al*. highlighted such changes by measuring hemodynamic changes in patients undergoing laparoscopic cholecystectomy [19]. They observed that the reverse Trendelenberg position ("head up") reduced the MAP by 17% and cardiac index by 14% when compared to the neutral horizontal position. Furthermore, the combined effect of insufflation and reverse Trendelenberg position was a reduction in cardiac index with an unchanged MAP. Despite these measureable changes, the European Association for Endoscopic Surgery practice guidelines concensus concluded that at intra-abdominal pressures up to 15 mmHg, the decrease in venous return and cardiac output is minimal and without consequence for healthy patients [20]. At this pressure, adequate volume loading mitigates the cardiovascular effects of the pneumoperitoneum, which are most pronounced during its induction [21].

Special consideration, however, is necessary for patients with limited cardiac reserve. In such patients, increases in heart rate and afterload coupled with an elevated SVR can potentially increase venticular wall tension, which may precipitate myocardial ischemia. When investigating the effects of laparoscopy on patients with severe heart disease [American Society of Anesthesiologits (ASA) class III or IV], Safran *et al*. noted significant elevations in SVR and MAP with a reduction in cardiac output at insufflation pressures of 15 mmHg [22]. These authors concluded that in patients with sig-

nificant pre-existing heart disease, insufflation causes a transient cardiac decompensation due to inadequate left ventricular reserve. Thus, for patients with limited cardiac reserve, the increased work necessary to maintain adequate circulation necessitates careful attention to the intra-abdominal pressure, volume status, and blood pressure to avoid potentially deleterious cardiovascular changes [20, 23].

Renal effects

Elevated intra-abdominal pressure also affects renal hemodynamics (Table 70.1). As early as 1923, Thorington and Schmidt noted in a bovine model that intra-abdominal pressures of greater than 15 mmHg and greater than 30 mmHg were associated with oliguria and anuria, respectively [24]. Similarly, in a study of 17 normal human volunteers, Bradley and Bradley observed a decrease in urine output after pressurizing a pneumatic abdominal girdle to 80 mmHg, which corresponds to an average intra-abdominal pressure of 20 mmHg. They observed that IVC pressure rose from 5.8 to 18.3 mmHg, with an associated reduction in effective renal plasma flow and glomerular filtration rate (GFR) [25].

Several mechanisms have been proposed to account for the renal dysfunction associated with increased intra-abdominal pressures. Thorington and Schmidt hypothesized that increased renal vein pressure is the etiology underlying renal functional changes [24]. Others speculated that direct renal compression accounts for the changes in renal blood flow (RBF) and functional impairment. Finally, changes in antidiuretic hormone (ADH, vasopressin) have been implicated as a cause of oliguria in patients with increased intra-abdominal pressure. However, decreased cardiac output, ureteral compression, and renal ischemia do not appear to contribute to laparoscopy-associated oliguria (21, 26–28).

Clinical experience with elevated intra-abdominal pressure secondary to bleeding or edema parallels that seen during laparoscopy. Richards *et al.* noted oliguria or anuria postoperatively in four patients who subsequently required re-exploration for bleeding associated with abdominal distention. In all four cases urine output remained low despite vigorous fluid resuscitation and normal-to-high arterial and central venous pressures. Operative decompression resulted in a prompt diuresis in each case [29]. Similarly, Fietsam *et al*. described an "intra-abdominal compartment syndrome" in four patients with massive retroperitoneal interstitial edema following abdominal aortic aneurysm repair who developed severe oliguria despite elevated central venous pressures [30]. With decompressive laparotomy, urine output increased significantly.

Animal models have implicated different possible etiologies underlying decreased RBF observed during laparoscopy. Harman *et al*. favored direct renal compression as the cause for decreased RBF and GFR in an experimental model of seven anesthetized dogs [21]. In this study, inflation of an intraperitoneal bag with air to a pressure of 20 mmHg resulted in a 22% reduction in GFR; at 40 mmHg, three dogs became anuric and the GFR in the remaining four dogs dropped to 7% of baseline. Likewise, RBF decreased from a baseline of 160 mL/min at 0 mmHg pressure to 36 and 9 mL/min at 20 and 40 mmHg intra-abdominal pressure, respectively. Furthermore, intravascular volume expansion had no effect on GFR or RBF. IVC and renal vein pressure correlated with intra-abdominal pressure, while renal artery pressure was relatively unaffected by variations in intra-abdominal pressure. With elevated intra-abdominal pressure, the increase in renal vascular resistance far exceeded the increase in systemic vascular resistance. These findings suggest that direct effects on the kidney, rather than changes in systemic hemodynamics, are responsible for the renal dysfunction seen with increased intra-abdominal pressure.

Other animal studies have implicated that increased intra-abdominal pressure during laparoscopy impacts renal hemodynamics. Chiu *et al*. measured the RBF in six pigs undergoing insufflation at varying levels of intra-abdominal pressure [31]. Using air as the insufflant, intra-abdominal pressure was gradually increased from 0 to 40 mmHg. Measurements of carotid artery blood flow (CABF) (representing cardiac output), carotid artery blood pressure (CABP), IVC pressure (IVCP) as a surrogate for intra-abdominal pressure, and RBF were recorded at various intra-abdominal pressures. Although CABP remained constant with increasing intra-abdominal pressure, CABF decreased linearly. Interestingly, renal cortical blood flow (RCBF) decreased exponentially with increasing intra-abdominal pressure. In contrast, renal medullary blood flow increased up to an intra-abdominal pressure of 20 mmHg and then dropped steadily as intra-abdominal pressure reached 40 mmHg. Moreover, the decrease in RCBF could not be accounted for solely by decreased cardiac output. Specifically, CABF decreased linearly with rising intra-abdominal pressure, whereas RCBF decreased exponentially. McDougall *et al*. utilized noninvasive magnetic resonance imaging (MRI) to similarly evaluate renal vessel blood flow [27]. These authors similarly demonstrated reduced cardiac output, reduced flow velocity in the renal vessels, decreased renal parenchymal perfusion, and reduced renal cortical and medullary blood flow associated with abdominal insufflation. Of note, while the exact mechanism by which RBP is impacted by pneumoperitoneum is not fully elucidated, the effects appear to be influenced by volume status. London *et al.*

noted that when subjected to an intra-abdominal insufflation pressure of 15 mmHg, pigs receiving only maintenance fluids had a 30% reduction in RBP, while those hydrated more aggressively had improved preservation of this parameter [32].

McDougall *et al.* further demonstrated in a porcine model that decreased renal vein blood flow is invariably associated with oliguria during laparoscopy [33]. At intra-abdominal pressures of 10 mmHg or greater, urine output, creatinine clearance, and renal vein flow decreased significantly despite minimal change in cardiac output. These effects were not gas specific; similar findings were observed with CO_2 or argon as an insufflant. Administration of renal doses of dopamine (2 μg/kg/min) and the use of ureteral catheters failed to overcome the effects of elevated intra-abdominal pressure. ADH was also measured, and no significant change was observed in any group despite increasing intra-abdominal pressure. Of note, 2 h after desufflation, ADH fell by 50% in all groups. Overall, these data suggest that impaired renal vein flow may be one mechanism accounting for the observed decrease in urine output.

During the early 1990s, a number of reports highlighted that patients undergoing lengthy laparoscopic procedures had significant intraoperative oliguria that resolved after desufflation [34, 35]. This is now a well-known clinical phenomenon. The role of ADH in promoting this oliguria is unclear. While there is a clear component of vascular and renal parenchymal compression, there is also evidence of increased ADH levels with pneumoperitoneum [36–38]. These studies have postulated that insufflation results in reduced preload, which contributes to lower right atrial volume and pressures. This in turn mediates release of vasopressin, which then acts on the distal tubule and collecting ducts to promote reabsorption of water. Rat models have noted that blocking the effects of vasopressin via a receptor antagonist can partially reverse the oliguria during insufflation [39].

In summary, the cause of decreased renal function observed during pneumoperitoneum is likely multifactorial.

Nonrenal visceral effects

Changes in blood flow observed with elevated intra-abdominal pressure are not limited to the kidney. Gastric mucosal perfusion can be assessed by gastric intramucosal pH and serves as a surrogate marker for splanchnic perfusion. Several groups have noted decreases in pH (and thus splanchnic flow) both during pneumoperitoneum as well as into the postoperative period. [16, 40]. Caldwell and Ricotta assessed blood flow to a number of visceral organs in dogs subjected to varying intra-abdominal pressures with an intraperitoneal inflatable bag [41]. Visceral blood flow decreased in all organs (stomach, small bowel, pancreas, colon, liver, spleen, and kidney) out of proportion to the decrease in cardiac output, with the exception of the adrenal gland. Similarly, Hashikura *et al*. measured blood flow to the liver and kidney in seven pigs subjected to intra-abdominal pressures of 6, 12, 18, and 24 mmHg during CO_2 insufflation [42]. At higher pressures, blood flow to the liver was significantly decreased. Since splanchnic ischemia is a known risk factor for bacterial translocation across the gut wall, it is not suprising that experimentally pneumoperitoneum has been associated with increased bacterial translocation from the peritoneum into the blood [43]. This phenomenon, however, has not been recognized as a clinical cause of laparoscopic morbidity.

Intracranial pressure

Laparoscopy has a well-documented impact on intracranial pressure (ICP). Both experimental [44–48] and clinical [49] studies have demonstrated an increase in ICP associated with CO_2 pneumoperitoneum. Although two clinical studies showed a direct correlation between ICP and PCO_2 [50, 51], Josephs *et al*. found in an animal model that the rise in ICP was independent of changes in arterial PCO_2, PO_2, pH, or MAP [44]. The Trendelenberg position appears to worsen the increase in ICP associated with insufflation, although the supine or reverse Trendelenberg position does not eliminate the observed increase [48]. Furthermore, Schob *et al.* observed that the rise in ICP with pneumoperitoneum also occurred with other insufflation agents (NO_2 and helium), although to a lesser degree than with CO_2 [52].

Several theories have been proposed to account for the rise in ICP observed during laparoscopy. One hypothesis incorporates the modified Monroe–Kellie doctrine, by which a change in one intracranial compartment [among four compartments: vascular, cerebrospinal fluid (CSF), osseous, and parenchymal] results in a compensatory change in the other nonosseous compartments. Rapid changes in one compartment, however, may preclude compensation, resulting in a rising ICP. Este-McDonald *et al*. postulated that abdominal insufflation can increase intrathoracic pressure, leading to obstruction of venous outflow from the spinal cord via the lumbar and pelvic plexuses [46]. The increased volume of the vascular intracranial compartment induces a rise in ICP. Others have theorized that impaired absorption of CSF accounts for the increase in ICP. This theory is further supported by the finding of impaired CSF absorption in anesthetized pigs in whom radioactive iodinated human serum albumin (RISA) was injected into the CSF. A reduced rate of CSF absorption (by 55%) was demonstrated by measuring RISA in the

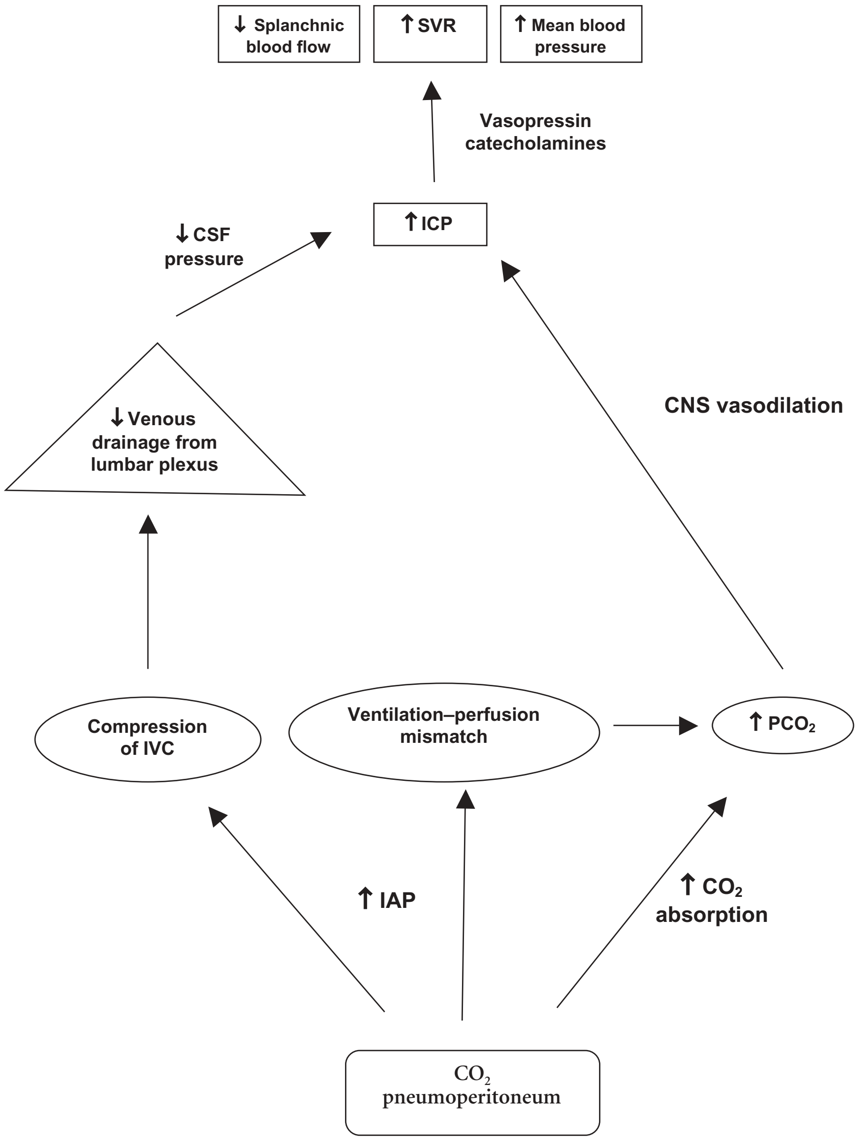

Figure 70.1 Model proposed by Rosenthal *et al.* to account for increased intracranial pressure and subsequent hemodynamic effects associated with CO_2 pneumoperitoneum. IAP, intra-abdominal pressure; IVC, inferior vena cava; CVP, central venous pressure; CNS, central nervous system; ICP, intracranial pressure; SVR, systemic vascular resistance.

blood over a 4-h period during CO_2 pneumoperitoneum to 15 mmHg pressure [53].

Conversely, Rosenthal *et al*. have postulated that the rise in ICP is mediated by a two-phase mechanism: (1) early, passive, venous effect, and (2) late, active, arterial effect (Figure 70.1) [45, 54]. In the early, mechanical stage, increased intra-abdominal pressure results in compression of the IVC with a resultant increase in CVP. This in turn impairs venous drainage from the lumbar plexus, thereby raising ICP. In the late stage, hypercarbia, due to ventilation–perfusion mismatch and peritoneal absorption of CO_2, causes vasodilatation of the intracranial vessels and a rise in ICP. Furthermore, acute elevation in ICP elicits a central nervous system response (Cushing reflex) mediated by release of catecholamines and vasopressin. The Cushing's reflex yields an increased MAP and SVR, while reducing splanchnic and visceral blood flow to ameliorate central venous return. Collectively, this array of hemodynamic changes may be accounted for by the rise in ICP.

The clinical significance of these observations in patients without pre-existing intracranial disease is unknown, although to date no cases of significant neurologic impairment directly attributable to pneumoperitoneum have been reported. However, for patients with a head injury or an intracranial lesion, the potential for increased ICP during CO_2 pneumoperitoneum could be dangerous. As such, laparoscopy may be

Table 70.2 Respiratory effects of increased intra-abdominal pressure (10–20 mmHg).

Respiratory parameter	Change
Peak inspiratory pressure	↑
Chest wall mechanical resistance	↑
Pulmonary compliance	↓
Alveolar dead space	↔ or ↑
Functional reserve capacity	↓
Forced vital capacity	↓
FEV_1	↓
Peak expiratory flow	↓

contraindicated in these patients or should be undertaken only under conditions of low intra-abdominal pressure or by gasless laparoscopy to avoid potentially dangerous elevations in ICP. Additionally, the use of intraoperative ICP monitoring in this situation is prudent [45, 46, 48].

Respiratory effects

Alterations in respiratory mechanics have also been noted with abdominal insufflation (Table 70.2). Specifically, increased intra-abdominal pressure impedes diaphragmatic excursion, contributing to decreased functional residual capacity and an increase in pulmonary dead space. As such, studies have documented that as airway pressures increase, pulmonary compliance (by nearly 50%) and functional reserve capacity decrease [16, 55, 56]. Motew *et al*. noted that the average peak airway pressure required to maintain a constant tidal volume in 10 women undergoing laparoscopy increased from 17.9 mmHg at 0 mmHg intra-abdominal pressure to 25.9 mmHg at 20 mmHg intra-abdominal pressure [57]. Such factors can contribute to hypoxemia if patients are allowed to breathe spontaneously during laparoscopic surgery. Controlled ventilation with adequate tidal volumes and incorporation of positive end-expiratory pressure (PEEP) can minimize alveolar atelectasis, thereby obviating ventilation–perfusion mismatch which contributes to hypoxemia [58]. Despite the considerations discussed above, the deleterious impact of pneumoperitoneum on intraoperative pulmonary mechanics is usually not clinically significant in healthy patients under general anesthesia [59]. However, in obese patients or those with lung disease, these perioperative changes can have deleterious effects, placing them at higher risk of pulmonary complications.

Finally, several studies have emphasized that postoperative pulmonary status following laparoscopy is favorable compared to an open surgical approach. Schwenk *et al*. reported on 60 patients who underwent laparoscopic (n = 30) or conventional (n = 30) resection of colorectal tumors and compared intraoperative respiratory mechanics [60]. These authors noted better forced vital capacity (FVC), forced expiratory volume in 1 s (FEV_1), peak expiratory flow, and oxygen saturation of blood in the laparoscopic group compared to the open cohort. Similar observations were made by Hasukic *et al*. in a surgical population comprised of open and laparoscopic cholecystectomy series [61].

Effects from absorption of CO_2

CO_2 homeostasis

Independent of the mechanical effect of increased intra-abdominal pressure, pneumoperitoneum can alter hemodynamic and respiratory parameters secondary to absorption of CO_2. To understand the potential impact of infusing CO_2 under pressure into the abdomen, a review of basic CO_2 homeostasis is requisite.

CO_2 is the predominant by-product of cellular metabolism. As such, an efficient mechanism for its elimination is required. The carbonic acid–bicarbonate system provides means for CO_2 removal, while buffering against marked changes in arterial pH. Both components of the system can be regulated: bicarbonate in the kidney and CO_2 in the lungs. CO_2 generated in tissues diffuses into capillaries. Less than 10% of this CO_2 dissolves in the blood and is transported to the lungs. The majority of the CO_2 (about 70%), however, combines with water in red blood cells to form carbonic acid in a reaction catalyzed by carbonic anhydrase. Almost as rapidly as it is formed, carbonic acid dissociates into hydrogen iond (which complex with hemoglobin) and bicarbonate ions (which diffuse into the plasma):

$$CO_2 + H_2O \rightleftarrows H_2CO_3 \rightleftarrows H^+ + HCO^-{}_3$$

The remaining minor fraction of CO_2 complexes with hemoglobin and plasma proteins for delivery to the lungs [62]. The carbonic acid–bicarbonate system therefore provides a powerful buffering system: the elimination of CO_2 drives the reaction to the left, thereby reducing the number of hydrogen ions and increasing pH. In addition, increases in CO_2 or hydrogen ion concentration directly stimulate the chemosensitive area of the medulla, leading to respiratory stimulation and consequently to increased excretion of CO_2 [62].

Irrespective of whether or not CO_2 is produced as a by-product of tissue metabolism or is instilled into the peritoneum for laparoscopy, it is absorbed into the blood and ultimately equilibrates in the lungs. The movement of gas from one body compartment to another is controlled by the process of diffusion, which generally occurs from an area of high concentration to an area of low concentration. The rate at which a dissolved gas in

liquid crosses an interface is determined by a number of factors, including the pressure differential across the interface, the solubility of the gas in the liquid, the distance the gas must traverse, the cross-sectional area of the fluid, the molecular weight of the gas, and the temperature of the gas and fluid. The *diffusion coefficient* defines the rate of diffusion of a specific gas for a given pressure differential and diffusion distance, thereby encompassing the solubility and molecular weight of the given gas. The diffusion coefficient is a relative number based on the diffusion coefficient of oxygen. The diffusion coefficients for several important respiratory gases are: O_2 1.00, CO_2 20.30, CO 0.81, N 0.53, and He 0.95. Clearly, CO_2 is more readily diffusible in body tissues than any of the other respiratory gases. This fact is central to choosing CO_2 as an ideal insufflant for laparoscopy. With establishment of a CO_2 pneumoperitoneum, the CO_2 partially dissolves in the peritoneal fluid and subsequently reaches equilibrium with the tissues and blood as determined by the diffusion coefficient.

Physiologic consequences of CO_2 absorption

The hemodynamic sequelae of hypercarbia have been characterized by Price into direct and indirect effects [63] (Table 70.3). Experimentally, lower pH (whether due to hypercarbia or otherwise) is associated with myocardial depression, resulting in decreased heart rate and force of contraction. Additionally, vasculature responds to a low pH by vasodilating. In contrast, CO_2 directly enhances sympathetic activity, which promotes cardiac contraction and induces peripheral vasoconstriction. Cardiac output and myocardial oxygen consumption increase in response to hypercarbia and may reflect increased sympathetic activity. Peripherally, increases in MAP are modest and suggest that local peripheral vasodilatory effects outweigh the central sympathomimetic effects. Clinically, Cullen and Eger evaluated the circulatory response to increased inhaled CO_2 in 42 healthy volunteers [64]. Like Price, they found increases in heart rate, stroke index, myocardial contractility, and peripheral blood flow; in contrast, total peripheral resistance dropped significantly.

CO_2 pneumoperitoneum has been implicated in hemodynamic and respiratory alterations observed during laparoscopy. Early investigators observed that patients allowed to breathe spontaneously during laparoscopy began to hyperventilate [65–67]. Conversely, patients managed by controlled ventilation developed hypercarbia and acidosis, necessitating ventilatory changes.

Alexander *et al.* illustrated these observations in a study of 24 healthy patients undergoing laparoscopy at 20 mmHg with CO_2 pneumoperitoneum [68]. When comparing arterial blood gases obtained prior to insufflation and during laparoscopy, they observed an increase in PCO_2 by 8.6 mmHg and a decrease in arterial pH by 0.082 pH units after insufflation. These same authors subsequently demonstrated that this effect occurred only with CO_2 insufflation and not N_2O insufflation, thereby implicating CO_2 absorption from the peritoneal cavity, rather than hypoventilation, as the etiology of the hypercarbia and acidosis [69]. Likewise, Hodgson *et al*. [65] and Montalva and Das [70] observed that patients undergoing laparoscopy at intra-abdominal pressures of 15–20 mmHg developed significant hypercarbia despite being maintained at a constant minute volume. Montalva and Das demonstrated an increase in PCO_2 of 5 mmHg from pre- to post-insufflation in 10 female patients undergoing laparoscopy at a working pneumoperitoneum of 20 mmHg [70]. Hodgson *et al*. found a difference of 8 mmHg in the PCO_2 measured before and after insufflation to 15–20 mmHg in patients breathing spontaneously during laparoscopy; while in 10 patients maintained at constant minute volumes, the mean change in PCO_2 was 10.1 mmHg.

Collectively, these data imply that at 15–20 mmHg CO_2 pneumoperitoneum, significant quantities of CO_2 are absorbed from the peritoneal cavity during laparoscopy. Additionally, the absorption of CO_2 appears to reach a steady state between 15 and 30 min after the initiation of insufflation. Tan *et al.* measured CO_2 elimination in 12 patients undergoing pelvic laparoscopy to estimate CO_2 absorption during insufflation [71]. CO_2 excretion increased from 146 mL/min prior to insufflation to 183 and 172 mL/min at 15 and 30 min after insufflation, respectively. This translated into a rate of CO_2 absorption from the peritoneal cavity of 42 and 39 mL/min, respectively. Likewise, Mullet *et al*. measured CO_2 excretion at 2-min intervals after insufflation in 20 patients undergoing laparoscopic cholecystectomy

Table 70.3 Hemodynamic effects of hypercarbia.

Hemodynamic parameter	Experimental effect: Direct effect*	Experimental effect: Indirect effect+	Clinical effect
Heart rate	↓	↑	↑
Cardiac contractility	↓	↑	↑ CO
Vascular resistance	↓	↑	↓ SVR
Mean arterial pressure	No data	↑	Slight ↑ BP

*Direct local effect of hypercarbia
+Indirect effect of hypercarbia secondary to sympathetic stimulation.
CO, cardiac output; SVR, systemic vascular resistance; BP, blood pressure.

(n = 10) or gynecologic laparoscopy (n = 10) [72]. In both groups, CO_2 excretion began to increase 8–10 min after the initiation of insufflation and reached a plateau by 15–20 min. The maximum increase in CO_2 excretion in the cholecystectomy group was 32 mL/min and in the gynecologic laparoscopy group was 18 mL/min, representing a 25% and 12% increase, respectively, from baseline.

Lister *et al*. further defined the relationship of CO_2 absorption during pneumoperitoneum in an experimental porcine model [73]. Twelve anesthetized pigs maintained at constant ventilatory parameters underwent CO_2 or helium insufflation in 5 mmHg increments from 0 to 25 mmHg. At each insufflation pressure, measurements were taken of CO_2 excretion (VCO_2), dead space, and hemodynamic parameters. In the CO_2 pneumoperitoneum group, CO_2 excretion increased in a nonlinear fashion with increasing intraperitoneal pressure, reaching a plateau at a pressure of 10 mmHg. In the helium pneumoperitoneum group, no increase in CO_2 excretion was noted. However, PCO_2 increased with rising intra-abdominal pressure in both groups, although the increase in PCO_2 was greater in the CO_2 group as compared to the helium group. Hemodynamic parameters were relatively stable at all pressures tested in both groups. The authors concluded that CO_2 absorption from the peritoneal cavity during insufflation reaches a maximum at a relatively low intra-abdominal pressure (10 mmHg). Until this point, there is a rapid increase in peritoneal surface area available for diffusion as intra-abdominal pressure increases. At higher pressures, limited additional surface area is available for further CO_2 absorption. However, PCO_2 continues to rise as a result of increasing dead-space ventilation. Finally, while the use of a helium pneumoperitoneum avoids the effects of direct CO_2 absorption from the peritoneal cavity, it produces the same ventilatory compromise secondary to increased intra-abdominal pressure.

In general, absorbed CO_2 is stored in the body tissues until it is eliminated by the lungs [74]. During brief periods of increased CO_2 absorption, alveolar and blood stores primarily mediate homeostasis. For longer intervals of CO_2 retention (i.e. during laparoscopy), skeletal muscle and visceral stores come into play as well [74]. The capacity of individual tissues to store CO_2 depends on their perfusion and storage capacity. Although bone is the largest potential reservoir, muscle may play a larger role in immediate CO_2 storage owing to its high perfusion rate [75]. According to Fowle and Campbell, an immediate storage capacity of approximately 40 mL for each mmHg rise in PCO_2 is available [76]. Therefore, if PCO_2 rises by 5–10 mmHg with a 20 mmHg CO_2 pneumoperitoneum, a corresponding 200–400 mL increase in CO_2 occurs. In the short term this excess CO_2 is buffered in the alveolar–arterial and visceral stores. However, potentially dangerous elevations in PCO_2 may result in serious hemodynamic alterations if compensatory changes in ventilation are not made. Furthermore, the need for elimination of excess CO_2 from visceral stores continues during the recovery phase after laparoscopy. With underlying pulmonary disease, elimination of CO_2 may be compromised, thereby necessitating prolonged mechanical ventilation in the postoperative period [77, 78].

Although hypercarbia associated with CO_2 pneumoperitoneum is recognized, the appropriate monitoring technique is controversial. Liu *et al.* prospectively evaluated 16 healthy patients undergoing laparoscopy using CO_2 pneumoperitoneum [79]. Capnography was used to measure end-tidal CO_2 during insufflation, while arterial blood gases were obtained intermittently to simultaneously assess arterial PCO_2. The authors noted good correlation between the two measurements. Specifically, end-tidal CO_2 increased from 31 to 42 mmHg while PCO_2 similarly rose from 33 to 44 mmHg during the procedure. Due to its noninvasive nature, capnography was recommended for monitoring healthy patients during laparoscopy. Wittgen *et al*. similarly observed concordance between capnography and arterial blood gas analysis in assessing PCO_2 in healthy patients undergoing cholecystectomy, but found capnography to be unreliable in estimating PCO_2 in patients with cardiopulmonary disease [77]. In 20 ASA class I patients, a small increase in PCO_2 and decrease in pH was noted after insufflation to 12–15 mmHg. Conversely, 10 ASA class II or III patients demonstrated a significant increase in arterial PCO_2 and decrease in pH after insufflation. However, no significant difference in end-tidal CO_2 was noted between the two groups after insufflation, suggesting that end-tidal CO_2 underestimated the arterial PCO_2 in the less healthy patients. Because of the poor correlation between end-tidal CO_2 and PCO_2 in patients with cardiopulmonary disease, invasive monitoring with arterial blood gas analysis is necessary to reliably evaluate them during laparoscopy.

The direct cardiovascular effects of hypercarbia are difficult to distinguish from sequelae due to increased intra-abdominal pressure during laparoscopy. Some hemodynamic changes occur irrespective of the insufflant, whereas others appear to be gas specific. In 10 healthy women undergoing laparoscopic tubal ablation, Motew *et al*. noted that CO_2 insufflation to 20 mmHg was associated with increased central venous and arterial pressure, tachycardia, and hypercarbia, although cardiac output remained unchanged [57]. Similarly, Liu *et al.* used transesophageal echocardiography (TEE) to measure cardiac output in 16 healthy patients undergoing laparoscopic cholecystectomy [79]. Although a significant rise in blood pressure was noted with insufflation, no change in cardiac output was measured.

Additionally, Marshall *et al*. noted no change in cardiac output in seven young women undergoing laparoscopic tubal ablation [80]. However, significant increases in central venous pressure, MAP, and heart rate occurred with insufflation to 15–21 mmHg. Other groups, however, have noted more substantial impacts on cardiac output and other measures of cardiovascular function [81, 82].

Several randomized trials compared the hemodynamic and respiratory consequences of high- and low-pressure CO_2 pneumoperitoneum during laparoscopic cholecystectomy. Wallace *et al*. randomized 40 patients to low-pressure (7.5 mmHg) versus high-pressure (15 mmHg) pneumoperitoneum and found no significant differences between the two groups with regard to PCO_2 or end-tidal CO_2, peak airway pressure, heart rate, cardiac index, stroke index, or MAP [83]. However, the decrease in cardiac index that was observed in both groups was greater and lasted longer in the high-pressure group. Somewhat in contrast, Dexter *et al.* observed that stroke volume increased from baseline in 10 patients undergoing low-pressure laparoscopy (7 mmHg) but decreased in 10 patients undergoing high-pressure laparoscopy (15 mmHg) [18]. Likewise, cardiac output remained at or below baseline levels in the high-pressure group. However, in the low-pressure group, after an initial decline in cardiac output, levels subsequently increased to 20% above baseline. These studies suggest that there may be a slight hemodynamic advantage to low-pressure laparoscopy.

Hemodynamic impact of patient positioning

Positioning during laparoscopy can influence hemodynamic parameters (Table 70.4). Williams and Murr demonstrated this in a canine experimental model by evaluating hemodynamic parameters in 10 dogs undergoing CO_2 insufflation in various positions [84]. In the horizontal position at pressures of 15 and 30 mmHg, cardiac output dropped to 79% and 77% of baseline, respectively. Positioning the animal head down resulted in a smaller reduction in cardiac output (86% of baseline at 15 mmHg, 82% of baseline at 30 mmHg) when compared to the horizonal position. Conversely, the head-up position further reduced cardiac output at both 15 and 30 mmHg pressure: 70% and 67% of baseline, respectively.

Table 70.4 Direct effects of patient position on hemodynamic parameters when compared to the supine position.

Hemodynamic parameter	Patient position: Head up	Patient position: Head down
Heart rate	↑	↓
Mean arterial pressure	↓	↑
Systemic vascular resistance	↑	↓
Cardiac output	↓	↑
Intracranial pressure	↓	↑

Similar observations have been made in a clinical setting. Joris *et al.* noted hemodynamic parameters to be position dependent in 15 patients undergoing laparoscopic cholecystectomy at an intra-abdominal pressure of 14 mmHg [85]. Hemodynamic parameters were measured before and after induction of anesthesia, after positioning the patient head up, at various time intervals after insufflation and after desufflation. Induction of anesthesia with the patient supine prior to insufflation resulted in a 9% decrease in MAP and a 25% decrease in cardiac index. Tilting the patient to the head-up position further reduced the MAP by 17% and the cardiac index by 14%. With insufflation, the MAP increased by 37% and the cardiac index decreased by 18% compared to the head-up position prior to insufflation. Overall, MAP was unchanged and the cardiac index decreased by 50% from the preanesthesia value (from 3.6 to 1.8 L/min/m^2 at 5 min after insufflation). SVR and pulmonary vascular resistance increased by 107% and 128%, respectively. The authors suggested that the reduction in cardiac index may have been caused by increased afterload (SVR), as well as decreased venous return. The increase in SVR was likely a consequence of increased venous and arteriole resistance arising from increased intra-abdominal pressure, as well as from enhanced sympathetic activity resulting from elevated PCO_2. This study comprehensively demonstrated the cumulative effects of anesthesia, patient positioning, and insufflation on the hemodynamic status of patients undergoing laparoscopy.

Kelman *et al*. compared hemodynamic parameters in 39 patients undergoing gynecologic laparoscopy in either the horizontal (n = 21) or head-down position (n = 18) [86]. In the horizontal position, cardiac output rose from 3.9 L/min before insufflation to 4.5 L/min after insufflation to 10–20 cmH_2O. Baseline cardiac output was higher in the head-down position (4.8 L/min) compared to the horizontal position (3.9 L/min). After insufflation to 10–20 cmH_2O, cardiac output increased to 5.3 L/min in the head-down group. At an intra-abdominal pressure of 30–40 cmH_2O, however, cardiac output fell in both groups (4.4 L/min in the horizontal position and 4.8 L/min in the head-down position). The authors postulated that the changes in cardiac output reflected changes in central venous pressure; namely, patients in the head-down position had higher central venous pressures than patients in the horizontal position, and the cardiac output was correspondingly higher.

Unlike Kelman *et al.'s* study described above, Hirvonen *et al*. observed a decrease in cardiac index from baseline in 20 female patients undergoing laparoscopic hysterectomy in the head-down position when insufflated between 13 and 16 mmHg pneumoperitoneum [87]. Increases in pulmonary arterial pressure, central venous pressure, and pulmonary capillary wedge pressure were also noted. Similar observations were subsequently made by this group when studying a cohort of patients undergoing laparoscopic cholecystectomy [88].

In summary, three variables influence hemodynamic parameters during laparoscopy: intra-abdominal pressure, choice of insufflant, and patient position. For patients undergoing laparoscopy in the supine position, cardiac output is unaffected or decreases slightly with insufflation to low-to-moderate intra-abdominal pressures (10–15 mmHg). Higher intra-abdominal pressures (>20 mmHg) adversely affect cardiac output by decreasing venous return. Furthermore, urine output can decline significantly, although returns to normal shortly after desufflation. The choice of insufflant further contributes to the net hemodynamic effect. CO_2 insufflation can cause hypercarbia, which has a stimulatory effect on the circulatory system, thereby increasing heart rate, stroke volume, and myocardial contractility, while decreasing peripheral vascular resistance. Conversely, absorption of inert gases such as helium generally manifest with no additional hemodynamic changes. The head-down position results in favorable hemodynamic changes. Here, cardiac output is higher than in the supine position, but is still dependent on intra-abdominal pressure. Of note, ICP increases in the head-down position, which could be potentially dangerous in select patients already at risk for increased ICP.

Stress response and immunologic factors

Trauma related to surgery is known to stimulate systemic inflammatory and immune responses. Furthermore, alterations in the stress and immune response correlate with the severity or extent of injury [89] such that the physiologic response to laparoscopic surgery may differ from that of open surgery. Additionally, insufflation (particularly by CO_2) may play a contributing role in systemic immune response.

Acute-phase reactants

The primary mediators of the acute-phase response are the inflammatory cytokines interleukin-1 (IL-1), IL-6, and tumor necrosis factor (TNF), which are released from peritoneal macrophages [90]. The hepatic component of the acute-phase response is regulated by IL-6, which stimulates production of acute-phase response proteins, including C-reative protein (CRP), which is the primary marker [91, 92]. TNF and IL-1β mediate the nonhepatic manifestations of the acute-phase response, such as fever and tachycardia [91].

IL-6 is an early marker of tissue damage and levels rise in proportion to tissue trauma. A number of investigators have compared serum IL-6 levels following laparoscopic and corresponding open operations. When specifically considering gallbladder removal, numerous series have demonstrated significantly higher levels of IL-6 associated with open versus laparoscopic cholecystectomy [93–95]. Some groups have also observed a correlation between peak IL-6 and CRP levels [96, 97]. In contrast, results for laparoscopic-assisted colon resection are less definitive. In a nonrandomized trial comparing laparoscopy-assisted with open colon resection, Harmon *et al.* detected reduced IL-6 levels with the laparoscopic approach [98]. Subsequently, Leung *et al.* reported a randomized trial of 34 patients with organ-confined rectosigmoid carcinoma managed by laparoscopy-assisted or open colon resection. These authors observed significantly lower IL-6 and IL-1β levels following laparoscopic surgery [99]. Conversely, Stage *et al.* measured higher levels of IL-6 and CRP in the laparoscopic cohort among a mixed group of patients randomized to laparoscopy-assisted or open colectomy [100]. It is likely that differences in patient and tumor characteristics in study groups account for the discrepancies in these studies.

CRP is one of the most extensively studied acute-phase reactants following surgery. CRP rises 4–12 h following surgery, peaks at 24–72 h, and remains elevated for approximately 2 weeks [101]. Most studies demonstrate modest increases in CRP following laparoscopic versus open surgery [94, 97, 99, 102–104], although a few groups observed no difference in acute-phase response proteins between the two groups [105, 106].

Influence of insufflation agent

The impact of specific insufflation agents on immune function has been studied both experimentally and clinically. Chekan *et al.* compared the immune competence of mice (determined by ability to clear an intraperitoneally administered intracellular pathogen) following abdominal laparotomy or laparoscopy with CO_2 or helium as insufflant [105]. All interventions were associated with impaired cellular-mediated immunity (decreased clearance of interperitoneal bacteria), although CO_2 pneumoperitoneum resulted in a lower bacterial clearance rate than either laparotomy or helium pneumoperitoneum. Of note, mice with helium pneumoperitoneum demonstrated the best clearance rates.

Similarly, West *et al*. demonstrated significantly lower levels of TNF and IL-1 in response to bacterial lipopolysaccaride when macrophages were incubated in CO_2 compared with air or helium [107]. They further proposed that the impairment in macrophage cytokine production was due to intracellular acidification as a result of the CO_2 pneumoperitoneum [108]. Conversely, Sandoval *et al*. found no impairment in natural killer cell activity in rats subjected to CO_2 pneumoperitoneum [109]. Clinically, Sietses *et al.* randomized 33 patients undergoing laparoscopic cholecystectomy to CO_2 insufflation, helium insufflation, or an abdominal wall-lifting technique, and measured systemic immune response [110]. These authors noted that CRP levels were significantly higher in the helium and abdominal wall-lifting groups, suggesting that incision size alone is not responsible for differential immune responses. Other variables related to the pneumoperitoneum have also been investigated to assess for effect on immune function. In a randomized clinical trial of laproscopic cholecystectomy, cytokine production was attenuated when using warmed compared with room temperature CO_2 [111].

Other markers

Beyond cytokine and inflammory markers, the stress response, as measured by neuroendocrine factors has been compared between laparoscopic and open surgery. In a randomized trial comparing laparoscopic and open cholecystectomy, Karayiannakis *et al.* detected significantly higher levels of cortisol, epinephrine, and norepinephrine in the postoperative period after open cholecystectomy [112]. Likewise, LeBlanc-Louvry *et al*. found reduced levels of adrenocorticotropin hormone as well as urinary cortisol and catecholamine metabolites in patients randomized to laparoscopic versus open cholecystectomy [113]. Conversely, Hendolin *et al*. found no significant differences in plasma cortisol or catecholamines between patients undergoing laparoscopic versus open cholecystectomy in a randomized trial [114].

Overall, the effects of CO_2 insufflation on the stress response continue to be discovered. There are divergent data regarding the effects of CO_2 on immune function. Further correlation of the immune and stress response and immunolgic outcome is required in order to determine their significance with regard to laparoscopic complications, postoperative recovery, and tumor implantation or metastasis.

Complications

Adverse effects can occur secondary to either the establishment or maintenance of pneumoperitoneum. Hemodynamic and ventilatory sequelae are discussed above. However, a number of complications can occur due to misplacement of the Veress needle and/or trocar with subsequent insufflation.

Subcutaneous emphysema is the most common manifestation of a poorly positioned Veress needle or trocar. In this case leakage of CO_2 around the trocar or direct insufflation of CO_2 into the subcutaneous or properitoneal tissues results in dissection of gas along extraperitoneal tissue planes. Generally, subcutaneous emphysema is harmless, but in certain instances it can lead to hypercarbia [115–117]. Wolf *et al.* found that subcutaneous emphysema was one of several factors, including increased duration of insufflation and an extraperitoneal approach, that correlated with increased CO_2 absorption (as measured by CO_2 excretion) during pelvic laparoscopy [115]. Unlike intraperitoneal gas, retroperitoneal or extraperitoneal gas is not limited by the peritoneal membrane. As such, it may traverse a variety of tissue planes to enter the pleural or extrapleural space, mediastinum, or pericardium. Dissection of gas along the great vessels or from the anterior neck allows entrance into the mediastinum [118]. From the mediastinum, gas may rupture into the pericardium or travel along the pulmonary vessels to the pleural space, resulting in pneumopericardium [119–121] or pneumothorax [118, 122, 123], respectively. Generally, in the absence of hemodynamic or respiratory compromise, small pneumothoraces may be managed conservatively. Large or symptomatic pneumothoraces are treated with needle aspiration or tube thoracostomy.

A potentially fatal complication of pneumoperitoneum is gas embolism [124–126]. Typically, the Veress needle is inadvertently positioned in a vein, resulting in infusion of gas directly into the venous system. The gas bubble travels to the right heart and lodges in the atrium or pulmonary arterial system. The gas lock may obstruct venous return to the atrium, resulting in a precipitous fall in cardiac output, or it may block pulmonary blood flow, causing pulmonary hypertension and right heart failure. The diagnosis is suggested by dramatic, sudden cyanosis, hypoxia, hypercarbia, arrhythmia, or hypotension during insufflation. The classic mill wheel murmur is pathognomonic, but variably present. Capnography may be useful in the early diagnosis of gas embolism [124, 127]. An abrupt decrease in end-tidal CO_2 may be the first sign of a gas embolism; the "air lock" completely obstructs pulmonary blood flow, leading to the decrease in CO_2 excretion [128]. However, the most sensitive means of detecting gas embolism is TEE, which can detect a bolus of CO_2 as small as 0.02 mL [129]. Experimentally, Couture *et al.* compared the sensitivity of TEE, end-tidal CO_2, pulmonary artery pressure, and precordial auscultation for detecting CO_2 embolism in anesthetized pigs, and found that TEE was superior to the other modalities, which were of comparable sensitivity, in detecting gas embolism [130].

Although venous gas embolism occurs most commonly as a result of Veress needle misplacement and insufflation into a large vein, embolism as a result of venous injury during pneumoperitoneum is also a theoretical concern [131, 132] Experimentally, O'Sullivan *et al*. detected gas emboli after 20 of 22 venotomies created in anesthetized pigs undergoing laparoscopy with CO_2 pneumoperitoneum at 10–25 mmHg pressure [129]. The degree of embolization correlated with the decrease in central venous pressure due to blood loss or distal venous compression, the duration and amount of manipulation of the venotomy, and intraperitoneal pressure. As such, in the event of significant venous injury during laparoscopy, intravascular volume should be maintained and the site of bleeding should be occluded directly.

Treatment of gas embolism consists of immediate desufflation, initiation of 100% inspired oxygen, and resuscitative measures. In addition, the patient is turned laterally and placed head down with the right side up. In this position further air is prevented from entering the pulmonary circulation and the air bubble can theoretically be aspirated with a central venous catheter placed in the right atrium.

Cardiac dysrhythmias have also been associated with laparoscopy. Carmichael reported three cases of marked bradycardia that occurred shortly after initiation of CO_2 insufflation [133]. He postulated that reflex vagal stimulation from stretching of the peritoneum accounted for the bradycardia. Two additional cases of cardiac dysrhythmia, both ventricular in nature, were also reported in this series. In these cases, ventilatory insufficiency was theorized to be responsible for the cardiac response. Scott and Julian reviewed 100 consecutive patients undergoing laparoscopy using CO_2 insufflation and compared them to 45 patients undergoing laparoscopy with N_2O insufflation [134]. Among the patients undergoing CO_2 insufflation, 17% experienced cardiac arrhythmias compared with only 4% of the N_2O patients. The arrhythmias were characterized primarily by extrasystolic ventricular beats. In addition, the postinsufflation PCO_2 was significantly higher in the CO_2 insufflation patients versus the N_2O patients, leading the authors to attribute the higher incidence of arrhythmias in the CO_2 group to the hypercarbia.

Low-pressure and gasless laparoscopy

Irrespective of insufflation agent, pneumoperitoneum can be associated with adverse effects attributable to increased intra-abdominal pressure and/or absorption of insufflant. In an attempt to avoid these potential problems, a number of investigators have examined the use of low-pressure pneumoperitoneum and gasless laparoscopy. Banting *et al*. described an abdominal lift device that suspends the abdominal wall, thereby reducing the intra-abdominal pressure needed to create a working space [135]. A 10–12-mmHg pneumoperitoneum was initially established and the lift device employed under endoscopic vision. An external hook-and-chain assembly secured to the side of the table was used to provide traction to suspend the anterior abdominal wall. They used this device in eight patients with cardiopulmonary disease; with use of the abdominal wall lift, a working pneumoperitoneum of only 6–8 mmHg was necessary to successfully perform cholecystectomy.

Araki *et al*. used a similar device in 151 patients undergoing laparoscopic cholecystectomy [136]. A low-pressure pneumoperitoneum (4 mmHg) was established to allow placement of the abdominal wall retractor. In 121 patients the abdomen was desufflated after the gallbladder was identified; in 30 obese patients the pneumoperitoneum was maintained until the cystic duct and artery were secured. No adverse effects were attributable to the abdominal wall-lift device. End-tidal CO_2 was recorded before pneumoperitoneum, during pneumoperitoneum, and after desufflation. End-tidal CO_2 was 29, 35, and 30 mmHg, respectively. Simarly, Kitano *et al*. prospectively randomized 83 patients with symptomatic gallstones to laparoscopic cholecystectomy using either traditional CO_2 pneumoperitoneum or a U-shaped abdominal lift retractor [137]. The laparoscopic procedure was completed in 88% of patients in the pneumoperitoneum group and in 100% of patients in the abdominal wall retractor group. When the gallbladder was severely fibrotic, the success rate was higher in the retractor group (100% of six patients) compared with the pneumoperitoneum group (12% of six patients). The authors concluded that the abdominal lift device was safer and more efficacious than traditional pneumoperitoneum for laparoscopic cholecystectomy.

Gasless laparoscopy has become easier with the development of commercial abdominal retractors/elevators secured to the side of the operating table (e.g. Laparolift, Origin Medsystems, Menlo Park, CA, USA). As in the studies noted above, all abdominal lift devices mechanically elevate the anterior abdominal wall away from the intra-abdominal organs, thereby creating a working space and eliminating the need for insufflation. Such instruments have been used for a host of laparoscopic procedures, including pelvic lymph node dissection, repair of a traumatic gastric perforation, herniorrhaphy, cholecystectomy, and appendectomy [138–140].

Conclusions

The vast majority of laparoscopic procedures can be safely performed with a CO_2 pneumoperitoneum. The

physiologic consequences of increased intra-abdominal pressure and absorption of CO_2 from the peritoneum are generally well tolerated in the healthy individual on controlled ventilation. Because of the problems of hypercarbia, alternative gases such as helium should be considered in debilitated patients with cardiopulmonary compromise. Finally, particularly in the high-risk patient or the patient at risk for increased intracranial pressure, gasless laparoscopy or low-pressure pneumoperitoneum may likewise provide comparable visibility and working space to the CO_2 pneumoperitoneum, but without the associated adverse consequences.

CHAPTER 71
Laparoscopy: Basic Instrumentation

Khaled Shahrour & Stephen V. Jackman

Introduction

Many advances in laparoscopy are due, in large part, to development of innovative laparoscopic instrumentation. Only the surgeon's imagination and the willingness of industry to produce new equipment limit the development of devices. Due to the progression of various modalities of laparoscopy, such as hand-assisted, robot-assisted, and single-port laparoscopy, specific instruments for these types of procedures will be discussed in their respective chapters. In this chapter, we describe the current state of the art in basic laparoscopic instrumentation with the goal of increasing the surgeon's knowledge of the devices available to assist them as part of any laparoscopic procedure. Many of these instruments and techniques for their use in certain procedures are described in detail in subsequent chapters.

Visual system

Excellent visualization is essential for optimal completion of the procedure. Fine dissection, the ability to anticipate instrument needs, and teaching are enhanced by the availability of this image for the surgeon and other participants. A high-resolution magnified image of the operative field (up to X20) is a significant advantage of laparoscopy [1]. The cost of such magnification is the limited two-dimensional (2D) field of view and the occasional loss of visualization due to fogging, soiling, or equipment failure. The components of the visual system include the endoscope, light source, camera, video monitor, and recording device.

Endoscopes

The conventional laparoscope is a rod–lens, fiberoptic, or camera-on-a-stick endoscope. They are available in fixed and movable configurations with straight (0°), angled (commonly 30°, 45°, and 70°), and flexible tips that can deflect in four directions. Working endoscopes are rarely used because of lower quality of images. Sizes range from 2.7-mm "needlescopes," that can pass through a Veress needle, to 12 mm in diameter. Light transmission decreases as angle increases and size decreases, which can be problematic, especially if there is bleeding in the field. A recent development is the LTF-VP EndoEye (Olympus, Center Valley, PA, USA), which is a 5-mm endoscope with a deflectable tip allowing 100° field of view in all directions (Figure 71.1).

Laparoscopists have to cope with the challenge of using 2D display to represent a 3D reality as depth perception is lost. 3D Systems with head-mounted displays or special glasses were developed in order to reproduce binocular vision. Most 3D systems have two lenses to maintain binocular vision. Although many studies have shown that 3D systems improve surgical task performance [2], the operator discomfort, high costs, and complicated instrumentation have limited the spread of the technology, except in robotics. Surgeons have complained of dizziness because of disparities in focus, zoom, and alignment between the two separate images of the two cameras [3].

Figure 71.1 (A) The LTF-VP EndoEye has a low profile handle; (B) the scope has a flexible tip with a camera-on-a-stick configuration (courtesy of Olympus Medical).

The Endosite 3Di visual system (Viking Systems Inc, San Diego, CA, USA) consists of a laparoscope with dual three-chip charge coupled device (CCD) cameras, and a headset worn by the surgeon. A "next generation" model with high-definition (HD) camera is being developed. A study compared 27 subjects with various laparoscopic experience performing three specific tasks (peg transfer, ring manipulation, and cannulation) on a standard laparoscopic trainer using standard 2D laparoscopes, the Endosite system, and the da Vinci Robotic system [4]. The authors concluded that there was improved performance with 3D optics in some complex tasks, such as peg transfer, but not in overall results.

A novel 3D system uses only one camera by using the difference in light density between objects. The system has a plate in the middle of the scope for turning the axis to bend the light. Using the plate, the images from two different paths of light corresponding to two images for the left and the right eyes are captured by the single camera. This novel technology is claimed to eliminate the possible dizziness that occurred with previous 3D systems [5].

Light source

Light is transmitted through the laparoscope via fiberoptic cable from the light source. Halogen, mercury, and xenon bulbs are the most common sources of high intensity light. Cool Wave (Wave Visions, Vadodara, India) is a light-emitting diode (LED) source that is available for use in laparoscopy with the advantages of lower energy consumption, longer life, and less heat production. Fiberoptic technology enables efficient light transmission between the light source and the tissue target. Integrated light source and camera systems allow for automatic adjustment of light intensity. Damage to fiberoptic cables will reduce light throughput and should be prevented. Transparent cables allow detection of cable damage.

Camera

The camera system consists of the camera box and camera head. The camera box processes the image for output to the monitors. Adjustments commonly include white balance, gain, zoom, light intensity, and shutter. The camera can be integrated into the laparoscope, either at the back or at the distal tip. The later configuration provides improved quality as the images are processed directly. The quest for better visual discrimination led to the development of single- and three-chip CCD cameras. Three-chip cameras provide better resolution and color but are heavier and more expensive. Comparison between HD, with a CCD at the tip, and standard definition laparoscopes showed improved image resolution (the minimum distance between two lines that can be identified at a certain distance), lower distortion (the alteration in the original image), greater depth of field (the in-focus distance range), and increased image luminous flux (light energy in a unit of time) with HD use despite having used a standard video monitor. The same study showed equivalent color reproduction (ability to match the original red, green and blue colors when they are recombined), grayscale discernment (represents the discrimination of shades of color), and field of view (the angular visual extent of an object at any moment) in both modalities [6]. Subjectively, many studies show that HD cameras contribute to improved

surgical task performance even when compared to standard definition three-chip CCD cameras [7]. The high cost of HD systems is a limitation.

Video monitor

Standard high-resolution cathode ray tube (CRT) monitors are increasingly being replaced by the lighter flat-screen liquid crystal display (LCD) monitors. This allows for easier and more ergonomic positioning using lightweight booms. Projection systems placing the image directly over the patient offer potentially the most intuitive images but suffer from lack of brightness and resolution.

Recording device

Any type of video capture device can be adapted to document laparoscopic procedures. Still photos and DVD are giving way to USB-based flash memory and portable hard drive recording devices.

Ultrasound probes

Most laparoscopic ultrasound probes have a linear-array transducer mounted on a flexible tip with a frequency range of 4.0–10.0 MHz [8]. They are useful for obtaining proper margins in procedures such as partial nephrectomy and cryoablation of renal tumors, especially if they are endophytic tumors.

Access system

Complications during laparoscopy may occur at the time of initial access to the abdominal cavity [9]. The closed technique using the Veress needle followed by blind insertion of a cutting trocar is replaced by safer techniques, including dilating-tip trocars, visual obturators, and variations of the open Hasson technique [10]. Balloon dissection may be used to rapidly develop retroperitoneal or retropubic spaces.

Insufflation

Pneumoperitoneum or pneumoretroperitoneum creates and maintains the working space for laparoscopic procedures, although many reports suggest that pneumoperitoneum is not necessary for safe access using an optical trocar [11]. CO_2 gas is used because of its availability, lack of combustibility, and solubility in blood. The acidosis caused by CO_2 is compensated by increased ventilation in all but the most severe pulmonary patients. These same patients are those for whom a large incision would be most detrimental postoperatively, and thus, poor pulmonary status is not an absolute contraindication to laparoscopic surgery. Helium, which is less soluble in blood, can be used in cases of severe hypercarbia. Other noble noncombustible gases are rarely used because of high costs and insolubility that may lead to gas embolus formation.

Insufflation pressure and gas flow are controlled with an insufflator. Initial gas flow rate is commonly set at 1–3 L/min until entry is deemed safe. The flow can then be increased to maximum (20–40 L/min), but will be limited by the size of the inflow device (Veress or port) and presence of partially-obstructing instrumentation in the device. Heated and humidified insufflations may reduce peritoneal irritation and pain [12].

Insufflation pressure is set initially at 15 mmHg and usually ranges between 8 and 20 mmHg during the case. Higher pressures improve working space and hemostasis, but the trade-off is higher gas absorption that can be a problem if not compensated by increased ventilation. Higher pressure can increase postoperative pain in minor procedures, but is not a factor in the majority of urologic laparoscopic procedures [13].

Veress needle: closed technique

Initial access to, and insufflation of, the peritoneal space is still commonly performed using a Veress needle (Figure 71.2). The needle consists of an inner

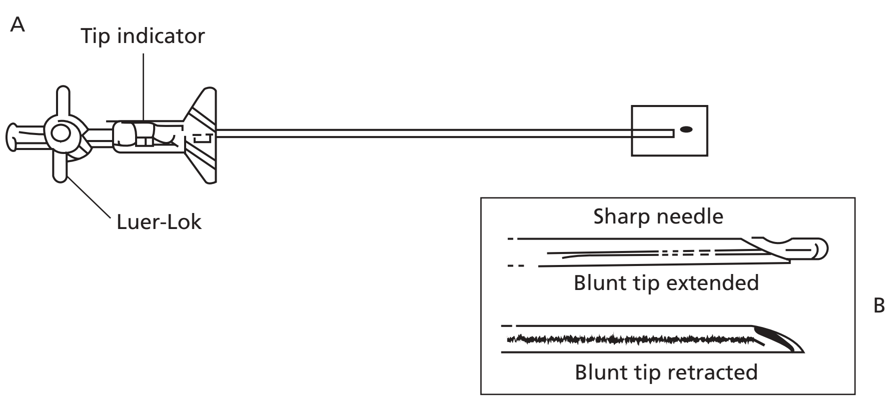

Figure 71.2 (A, B) The Veress needle tip has an inner blunt core that retracts when encountering resistance from tissue, but pops forward once the needle is in the peritoneal cavity.

spring-loaded blunt tip and an outer sharp sheath. The blunt tip is compressed and the sharp sheath is exposed when the needle is pressed against firm structures such as fascia. The blunt tip then springs out to prevent injury to more compliant structures, such as bowel. Reusable and disposable versions are available. Veress needles allow rapid access to the virgin abdomen in multiple possible locations. In patients with a history of prior abdominal surgery, it can often still be used safely if inserted in the quadrant furthest from possible adhesions [14].

Trocars

Trocars maintain pneumoperitoneum and allow fast and safe introduction of instruments into the abdominal cavity. Trocars typically contain an outer sheath and an inner sharp obturator. There are various sizes and lengths of disposable and nondisposable trocars ranging from 3 to 20 mm. An ideal trocar should cause decreased tissue injury, bleeding, trocar-site pain, and risk of herniation, in addition to having an easy entry and tight fascial seal to prevent dislodgments and gas leak, and eliminate wound closure. Cutting trocars offer rapid access to the peritoneal cavity, but their safety in initial port placement is questioned, especially in the previously operated abdomen. Even in secondary port placement under direct vision, there exists a risk of laceration of body-wall blood vessels. Transillumination is useful to detect blood vessels, but is not possible in many cases. Also, the fascia needs to be closed if a cutting trocar of 10 mm or larger is used.

Dilating-tip or nonbladed trocars are preferred as they do not cut through the abdominal wall. The tips are typically cone shaped, often with laterally placed fins to assist in the dilation of the abdominal wall muscles. Advantages include smaller fascial openings after port removal not requiring closure, with less chance of hernia and a higher likelihood of pushing aside rather than lacerating blood vessels and muscles [15]. Disadvantages include a higher insertion force and increased difficulty penetrating compliant structures such as the peritoneum and bladder [16, 17].

One of these noncutting trocars is the Step Needle/Sleeve trocar system (US Surgical, Norwalk, CT, USA); after being inserted with a small needle port, its sleeve expands with passage of a dilating obturator up to 12 mm (Figure 71.3). The fascial defect caused by the Step trocar is 50% smaller than that of cutting trocars [18]. The price of the trocar system has limited its widespread application, although it had lower rates of wall bleeding and of dislodgment without any herniation, despite nonclosure of the port site, in a prospective randomized trial of 250 patients [19].

Figure 71.3 Mesh sleeve of the Step System (US Surgical, Norwalk, CT, USA) can be placed in an open fashion or used with a Veress needle as shown. The cannula and dilator are then passed through the sleeve (copyright © 2011 Covidien. All rights reserved. Used with the permission of Covidien).

Figure 71.4 The Visiport (US Surgical, Norwalk, CT, USA) uses a recessed blade that extends out of the end of the obturator as the surgeon fires a trigger.

Visual obturators are systems combining a sheath, a cutting or dilating element, and a laparoscope, to allow direct visualization of the layers and blood vessels of the body wall during entry (Figures 71.4 and 71.5). The Optical Separator (Applied Medical Inc, Rancho Santa Margarita, CA, USA) is one such device. Its clear tip allows the surgeon to pass an endoscope into the trocar

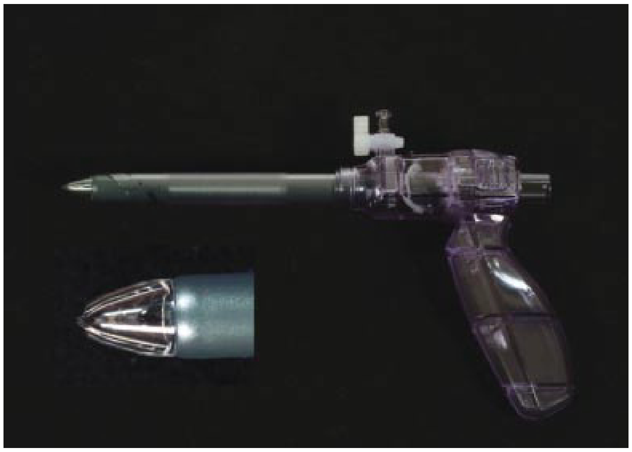

Figure 71.5 The Optiview (Ethicon Endo-Surgery, Cincinnati, OH, USA) uses two sharpened plastic fins on the tip of the trocar.

to monitor its passage through the abdominal wall. These devices can also be used initially for insufflation, as mentioned above.

Open access devices

Open access to enter the abdominal cavity is a viable option, particularly in pediatrics and patients with prior surgery. Disadvantages include the possibility of gas leak, having a larger incision than needed, and increased difficulty in obese patients. The Step system can be used in a modification of this method to solve some of these problems by inserting the mesh sleeve and dilating it after making a 2–3-mm incision of fascia and peritoneum.

Another modification of the Hasson technique for access to nonperitoneal locations is use of a balloon to rapidly develop the space. The Preperitoneal Dissection Balloon System (US Surgical) and Spacemaker II Balloon Dissector (US Surgical) allow direct observation during space creation (Figure 71.6). The initial incision needs to be sealed by a balloon-tipped or Hasson trocar. The Blunt-tipped Trocar (US Surgical) is a significant advance over the standard Hasson trocar as the balloon at the distal end holds it in place and the sliding foam ring proximally seals it to the abdomen (Figure 71.7).

General instrumentation

Articulated versus nonarticulated instruments

Part of the difficulty in performing certain laparoscopic tasks such as intracorporeal suturing and knot tying is due to the fact that conventional laparoscopic instruments are not articulated. Robotic technology allowed the use of the flexible EndoWrist technology, which pro-

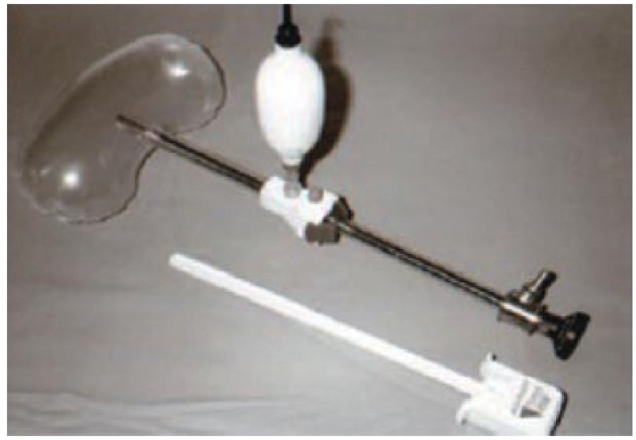

Figure 71.6 With the Preperitoneal Distention Balloon System (US Surgical, Norwalk, CT, USA), the retroperitoneal space can be balloon developed under direct vision.

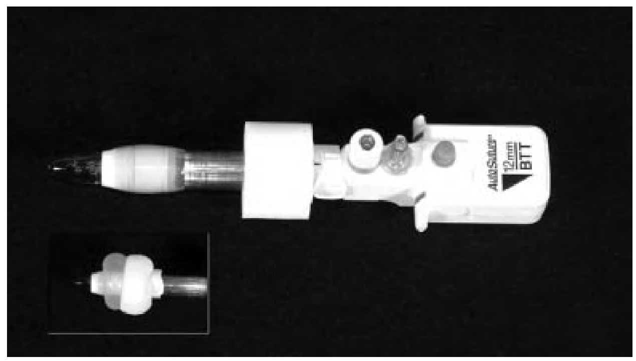

Figure 71.7 The Blunt-tipped Trocar (US Surgical, Norwalk, CT, USA) uses a balloon, which is inflated after insertion through the entry site, and a sliding foam collar to seal the trocar site at the fascia. Only a small amount of the trocar protrudes into the working space.

vides equivalent degrees of freedom (DOF) to that of open surgery. Handheld articulating instruments have been developed to reproduce the extra DOF available in robotics. Such instruments may facilitate intracorporeal suturing, especially in difficult positions such as the deep pelvis, and have a potential role in single-port surgery to assist in re-establishing triangulation [20]. However, the complexity of instrument maneuvering may make it harder to predict the movement outcome and coordination between the hand and tool. Also, another disadvantage of these instruments is that they inherently lack sufficient strength to provide robust retraction and dissection. A novel approach to make up for the weaknesses of articulation is the use of bent instruments such as HiQ LS (Olympus), which have a double curved shaft. The benefit of reticulating and bent instruments is more relevant in single-port surgery than conventional laparoscopy.

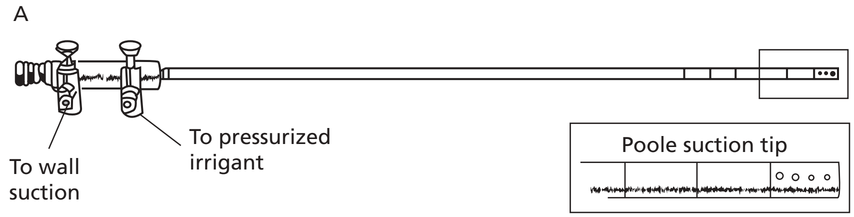

Figure 71.8 (A) Combined irrigator–aspirator has a trumpet valve mechanism for separately activating irrigation and suction; (B) Poole suction tip.

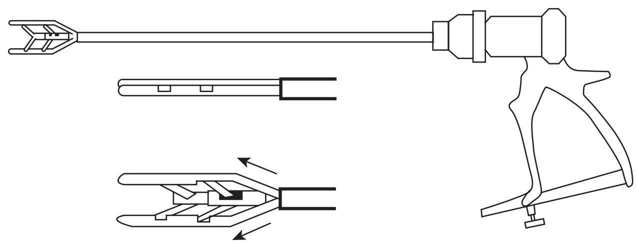

Figure 71.9 Reusable PEER retractor (Jarit Surgical Instruments, Hawthorne, NY, USA) is available in 5 and 10 mm sizes, which expand to provide a 20+ or 40+ mm surface for retraction.

Irrigator–aspirator

The irrigator–aspirator is an essential tool for both cleaning up the operative site for optimal visualization as well as dissection. The Poole suction design and blunt tip of most devices minimize impaction of tissue by the device and allow gentle bursts of suction to be used to tease tissue planes apart (Figure 71.8).

Retractors

Safe retraction of organs, such as the liver and bowel, is often necessary for access to the operative site. When adequate gravity retraction is not possible, numerous instruments are available. Expanding retractors are variations on the design of a straight 5- or 10-mm instrument that transforms into a wider configuration once inserted and can be attached to a table mount (Figure 71.9).

The Diamond Flex 80-mm Angled Triangular Liver Retractor (Genzyme Surgical Products Corporation, Tucker, GA, USA) is a long multijointed instrument that passes through a 5-mm port and then transforms into a rigid triangular shape after tightening its knob (Figure 71.10). Disadvantages include the initial cost and the metal construction that does not hold organs as securely as some disposable devices. Other variations of retractors, such as balloon, fabric, and fan, are available from several manufacturers. There are also needleoscopic or peanut retractors. Retraction of some structures during laparoscopy can be accomplished using a suture on a straight needle passed directly through the skin and anterior abdominal wall, around the structure, and back through the abdominal wall.

Instrument holders

Several mechanical instrument holders have been developed to take the place of the assistant. The instrument is positioned and locked in place. Camera holders can be either active (motorized) or passive (without a motor), while instrument holders are only passive. The basic Martin Arm (Mick Radio-Nuclear Instruments Inc, Mount Vernon, NY, USA) is a multijointed stainless steel arm requiring each joint to be positioned and hand tightened. The Unitrac Retraction System (Aesculap, Center Valley, CA, USA) uses compressed air to allow pneumatic locking with a single button (Figure 71.11). Other similar instruments include the Endoholder (Codman Inc, Cincinnati, OH, USA) and the TISKA Endoarm (Karl Storz, Endoskope, Tuttlingen, Germany), which assist with trocar and instrument positioning at a fixed point at the trocar puncture site. The Endoholder is an adjustable spring-loaded articulating holder that has a precision clamp to accommodate instruments of various sizes. The Flex Arm (Mediflex Surgical Products, Islandia, NY, USA) is a table-mounted flexible metallic arm that can hold retractors, instruments, and endoscopes in position, thus lowering the need for an experienced assistant. The disadvantages of these holders include the inability to determine the force that is applied to the instrument and the need to manually readjust their positions when needed.

Active camera holders have diverse interfaces to allow their control by the surgeon. The interface can be voice, foot, or hand controlled, or automatic instrument tracking. Active or robotic camera holders such as FreeHand (Prosurgics, Cupertino, CA, USA) allow the surgeon to control the endoscope with gentle, natural head movements, and replace the need for an experienced assistant to hold the camera. The LapMan (Medsys, Gembloux, Belgium) is a hand-controlled holder using a joystick that is placed under the surgeon's glove.

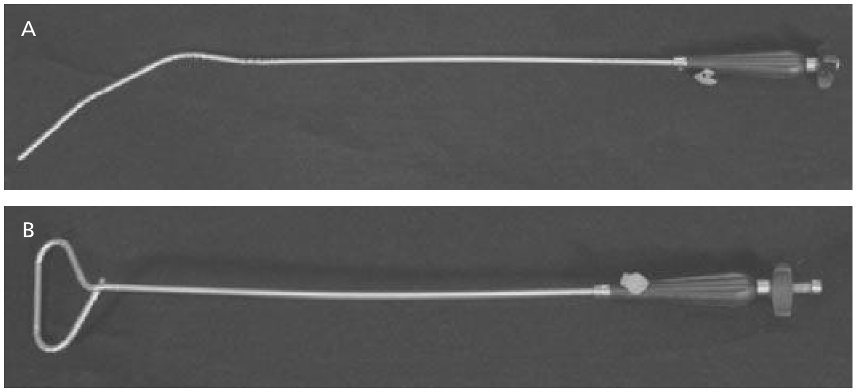

Figure 71.10 (A) Diamond Flex 80-mm Angled Triangular Liver Retractor (Genzyme Surgical Products Corp, Tucker, GA, USA) fits through a 5-mm cannula. (B) Twisting the handle converts the retractor to a rigid, angled triangular shape with large surface area.

Graspers and dissectors

Basic laparoscopic grasping, dissecting, and cutting instruments are available from many manufacturers and are quite similar. They vary in size (2–12 mm), handle type (inline or scissor grip), action (single or double), jaw curvature, ability to lock, rotate or reticulate, and presence of insulation for electrocautery use. The tips vary between blunt, pointed, curved, angled, and straight. The surface of the jaws can be traumatic (toothed) to hold tissue or atraumatic (smooth or serrated) for gentle tissue manipulation.

Five-millimeter scissor-handle, rotating, insulated, curved jaw instruments are the most commonly used. High-use basic instruments include the curved atraumatic grasper (Maryland type), atraumatic locking bowel grasper, curved scissors, and hook electrode. Laparoscopic peanuts are frequently used for blunt dissection between planes [21]. Surgeons develop their own preferences in choosing specific instruments with training and experience.

Incising instruments

Various modalities and instruments are used for incising tissue in laparoscopy. Some of these incising instruments, such as the scalpel or scissors, have limited or no hemostatic action, while other instruments have a combined action, such as ultrasound instruments (see below). Curved-tip laparoscopic scissors are the main type used for dissection, either mechanically (cold cut) or electrically (hot cut). A laparoscopic scalpel is available, although its role is very limited and its safety is questionable. Electrosurgical incision is done through various electrode configurations; needle, spatula, cutting, and hook. The thinner the metallic tip of the probe, the higher the density of the electrical current and thus the greater the cutting power.

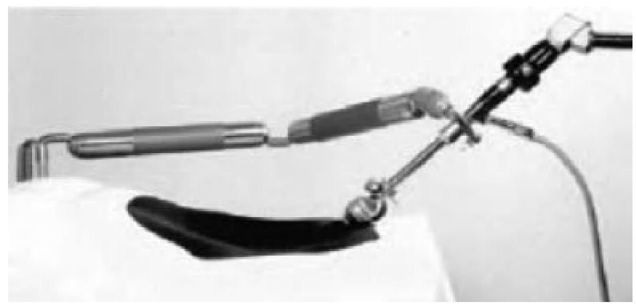

Figure 71.11 Unitrac Retraction System (Aesculap, Center Valley, CA, USA) is locked into place with compressed air. It can hold various instruments for retraction (courtesy of B. Braun Medical Ltd).

Laser

CO_2, neodymium:yttrium–aluminum–garnet (Nd:YAG), holmium, and potassium titanyl phosphate (KTP) are the lasers that can be used for incision and cutting through the working channel of the laparoscope. Some types, such as the holmium:YAG, can coagulate tissue at the same time. However, laser is not used frequently in laparoscopic urology.

Specialized instrumentation

Hemostatic instruments

Energy-based instruments

There are multiple instruments that employ different energies to seal tissue. These devices also use various feedback mechanisms, except for the conventional monopolar electrocautery, which does not have any feedback mechanism. In general, energy is delivered in a high-voltage and low-current burst that is combined with a feedback mechanism from the energy source to

evaluate the tissue and the corresponding current that is needed.

Electrocautery

Monopolar cautery is a high-frequency current delivered from a single electrode at the site and is used mainly for hemostasis of small vessels during dissection. Undiagnosed injuries from stray energy occur when the monopolar current is not completely localized to the visible part of the instrument, due to either unrecognized breaks in the insulating coating or to capacitative coupling [22]. Monopolar electrocautery accounts for more than half of the reported laparoscopic bowel injuries [23]. Active electrode monitoring (AEM) or insulation scanners can minimize cautery injury. The AEM System (Electroscope Inc, Boulder, CO, USA) includes laparoscopic instruments that are simultaneously connected to an electrocautery machine and to a separate device that searches for stray energy. The AEM System deactivates the generator once stray energy is detected. InsuloScan (Medline Industries Inc, Mundelein, IL, USA) tests the integrity of the insulating coat prior to the start of the procedure. Vigilant surveillance of electrosurgical instruments is key to preventing thermal injury. Bipolar current has low amplitude and voltage with a continuous waveform. Only the tissue grasped is cauterized because the current is restricted to between the instrument tips that are in contact with the tissue.

The LigaSure vessel-sealing system (Valleylab, Boulder, CO, USA) consists of a grasper connected to a radiofrequency generator. The electrical generator delivers a continuous low-voltage waveform with high-current flow. When a vascular structure is grasped, there is a feedback-response system that subsequently delivers the optimal energy required to seal the vessel. The vessel degrades quickly, causing a protein seal as collagen and elastin fuse because of the high current and low voltage. This mechanism leads to less charring and collateral thermal damage [24]. There is a blade in the jaws to safely divide the obliterated tissue. Vessels up to 7 mm in diameter are effectively sealed with the device [25]. The Gyrus PK Tissue Management System (Gyrus Medical, Minneapolis, MN, USA) is another hemostatic device that uses bipolar energy to seal tissue by melting collagen and elastin. In comparison to the LigaSure system that uses continuous energy, the Gyrus PK uses pulsed energy.

The EnSeal PTC Tissue Sealing and Hemostasis System (SurgRx, Redwood City, CA, USA) also uses bipolar energy, but with a nanotechnology feedback mechanism to reduce thermal spread. The cutting mechanism is in the shape of an "I" beam, utilizing high and equal tissue compression to enhance the seal as the blade is advanced along the length of the jaw. Nanoparticles modulate the current at the tissue–electrode interface as they interrupt the current flow when the temperature exceeds 100° C. Denes *et al*. evaluated the vessel-sealing performance of the EnSeal in a porcine model and reported that the sealed vessel walls of vessels less than 7 mm in diameter are capable of withstanding mean burst pressures greater than 900 mmHg [26]. Clinical studies demonstrated the efficacy of the EnSeal in laparoscopic nephrectomy and radical prostatectomy [27].

Lamberton *et al*. compared various bipolar modalities by measuring the lateral thermal spread, time to seal, burst pressure, and smoke production when used on 5-mm bovine arteries. They authors found that the LigaSure had the highest burst pressure and fastest sealing time; the Harmonic scalpel (Ethicon Endo-Surgery, Cincinnati, OH, USA), produced the least thermal spread and smoke but had the lowest mean burst pressure; the Gyrus PK had the highest smoke production with variable burst pressures; and the EnSeal was found to be the slowest with variable burst pressures (Table 71.1) [28].

Monopolar radiofrequency

The Endo FB3.0 Floating Ball (Salient Surgical Technologies, Portsmouth, NH, USA) can help in hemostasis of the parenchyma during partial nephrectomy. As a conductive fluid drips from the tip of the device, radiofrequency energy is transmitted through the fluid to the tissue at the point of tissue contact. Collagen in tissues shrinks, stopping blood flow in treated tissues [29]. Fluid is used to increase the contact area and to cool the tissue to prevent charring by keeping the temperature of tissue below 100° C.

Ultrasound

Ultrasound energy is used to achieve precise cutting and coagulation while avoiding the use of monopolar cautery. Electrical energy is transformed into vibration by the use of a piezoelectric crystal system. With the Harmonic scalpel , energy is delivered using a laparoscopic hand-piece with a shaft tuned to conduct the ultrasonic vibration at a rate of 55 000 cycles/s. The vibration produces heat, which is precisely located along the active jaw but the temperature is much lower than with conventional cautery at 50–100° C. This causes cavitation to a short depth of penetration of 1 mm [25]. When the surgeon activates the Harmonic scalpel, tissue is compressed between the jaws, blood vessels are occluded, and vibration causes intracellular vaporization. Proteins are denatured in the tissue and protein coagulum forms to seal the blood vessel while tissue is divided. Water vapor, rather than smoke, is emitted in

Table 71.1 Evaluated parameters for four hemostatic methods (adapted from Lamberton *et al.* [28]).

Publisher's Note:
Table not available
in the electronic edition

the abdomen. Disadvantages of the Harmonic scalpel include its slow action and the need to avoid direct contact with surrounding bowel, as the metallic jaw becomes hot during activation. SonoSurg (Olympus) is a similar device.

Another type of ultrasound device is the cavitational ultrasonic aspirator (CUSA; US Surgical). This device can be used to dissect high water content tissue but it is not used frequently due to the lack of hemostasis and slow action.

Argon gas coagulation

The argon beam coagulator (Conmed, Utica, NY, USA) is useful to treat solid-organ bleeding, such as in the liver, kidney, or spleen. This noncontact system uses a stream of argon gas to improve the delivery of monopolar electrosurgical current; argon is ionized by the current and this makes it more conductive than air. Argon is an inert colorless noncombustible gas that is safe to use with electricity, and it clears the body rapidly. Also, the argon flow improves visualization and coagulation delivery as it disperses blood during coagulation. An insufflation port should be opened during argon coagulation as it can increase the intra-abdominal pressure and lead to gas embolism [30].

Mechanical hemostatic instruments

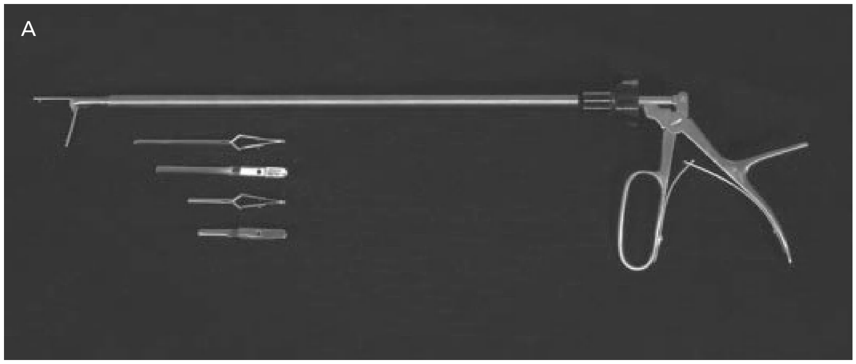
Temporary vessel occlusion clamps

Instruments that provide temporary occlusion of the renal artery have made laparoscopic partial nephrectomy possible. Endoscopic bulldog clamps are applied through a 10-mm trocar (Figure 71.12). The jaws range between 17 and 45 mm and can be either curved or straight. However, bulldog clamps sometimes do not provide adequate consistent occlusion of the renal vessels and in such cases, such as large or calcified renal arteries, two bulldog clamps can be used. Laparoscopic Satinsky clamps are also available but require an additional 5- or 10-mm flexible trocar or direct percutaneous placement. One drawback of hand-held clamps like the Satinsky clamp is that they may not provide equal distribution of the applied pressure on the blood vessels as they do not follow the contour of the kidney. An *in vitro* study comparing laparoscopic hand-held clamps, such as the Satinsky and DeBakey, to laparoscopic bulldog clamps using a load-cell device showed that the former have stronger occlusive force and that the proximal position of any clamp is associated with the strongest occlusive force [31]. Of note, all vascular clamps, except the silastic rubber vessel loop, were shown to cause endothelial vascular injury in a canine model [32].

The Simon Renal Pole Clamp (Aesculap, Center Valley, PA, USA) is a recently developed instrument that clamps the renal parenchyma to establish regional ischemia in the kidney. The clamp has two wide gently-curved ridged blades and fits a 10-mm trocar. Simon *et al.* reported their successful experience using this instrument in three elective laparoscopic partial nephrectomy cases [33]. The main potential advantage of such a clamp is the maintenance of a bloodless field, while avoiding the risks of hilar dissection and the whole-kidney ischemia of clamping.

Surgical clips

Most clips are made of titanium and are used to occlude small vessels. Clip appliers are mostly single use and multiload with 15–30 clips per load (Table 71.2). The multiloaded single-use applier can save time and decrease blood loss. The diameter of the rotating shaft generally depends on the size of the clips, which ranges from 5 to 11 mm, although there is a 5-mm disposable applier that provides 9-mm clips. Right-angled clip appliers offer better visualization in certain situations when the straight tip cannot be seen (US Surgical).



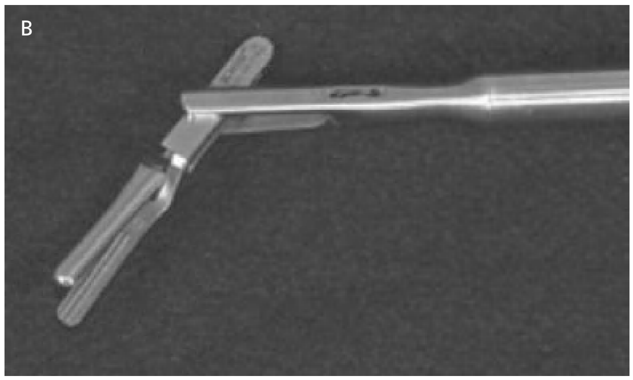


Figure 71.12 (A) This 10-mm applier allows laparoscopic placement of a vascular bulldog clamp. (B) The Klein applier (Klein Surgical Systems, San Antonio, TX, USA) also allows rotation and angulation of the bulldog clamp.

Table 71.2 Clip appliers (multiload, automatic clip loading, single use).

Hem-o-lok clips (Teleflex Medical, Research Triangle Park, NC, USA) are nonabsorbable radiolucent polymer locking clips. They are available in various sizes to ligate tissue ranging from 5 to 16 mm (Figure 71.13). The Auto Endo 5 (Teleflex Medical) is a new automatic applier preloaded with 15 medium clips. Although absorbable clips exist, there is no evidence of less adhesion formation with their use [34].

Tacking staplers

The laparoscopic biting stapler is useful in refashioning the peritoneum in laparoscopic ureterolysis and fixing mesenteric defects in bowel resections. The staples are made from titanium with sharp ends that enter the tissue and then undergo deformation into a rectangular shape or deploy as a cork-screw to secure the tissue. The most common devices are single use, multiload with 15–30 staples per unit, have a 360° rotating shaft, and may be articulated.

Linear staplers

These devices are essential for rapid and safe intracorporeal tissue division and reapproximation. They release multiple, closely-spaced, parallel rows of titanium

staples. There are different color-coded loads: thin or vascular, medium, and large or thick. Depth of tissue penetration of thin staples is around 2.5 mm as they deform to an exaggerated B-shape. These staples are ideal for rapid division of vascular pedicles. Medium-to-large staples are 3.0–4.8 mm thick when closed and are useful in thick tissue such as bowel, bladder, and ureter. Large staples should not be used for hemostasis as they do not fold as tight as thin ones.

Noncutting staplers fire three to four parallel rows of staples, and are useful for closing enterotomies. The Endo TA (US Surgical) is a linear noncutting stapler that is used in laparoscopic donor nephrectomy to provide a longer donor vein as the staples are placed on the donor side only. Cutting staplers deploy loads with six intercalated parallel rows of staples. A knife follows the staples and incises between them, leaving three rows of staples on each side. They are distinguished by the length of the staple line, ranging from 30 to 60 mm, and whether the heads are articulated or not. The Endo GIA Universal linear cutting stapler (US Surgical) is a universal firing device accommodating articulating and nonarticulating loads of various lengths. The ETS-Flex 45 stapler (Ethicon, Somerville, NJ, USA) has similar qualities to the Endo GIA (Table 71.3).

Figure 71.13 Hem-o-lok polymer clips (courtesy of Teleflex Medical, Research Triangle Park, NC, USA).

Loop ligation

Loop ligatures are useful in securing an already transected pedicle. A suture with a preformed sliding, locking knot is passed intracorporally. The structure to be ligated is then passed through the loop with a grasper, and the loop is cinched down with a knot pusher. There are a variety of sutures ranging from plain gut to synthetic absorbable sutures. Port choice is important as the pusher is of fixed length.

Hemostatic agents

Tissue damage activates thrombin from the inactive prothrombin. The activated thrombin cleaves fibrinogen into fibrin monomers that polymerize into fibrin strands that form the actual clot. Coagulation factors have adhesive as well as hemostatic properties. Fibrin in the wound promotes healing by supplying a network for growth of fibroblasts and macrophages [35]. Human thrombin and fibrinogen are applied separately to a bleeding site, resulting in the formation of a layer of fibrin that controls the bleeding and seals tissue. Fibrin tissue adhesive (FTA) is useful in treating complications of laparoscopic surgery, including spleen and liver injury, urinary fistula, and wound dehiscence [36].

Fibrin agents

Commercial preparations reproduce the final step of coagulation, resulting in adhesive, hemostatic, and healing effects through polymerization of fibrin chains with collagen of adjacent or damaged tissue [37]. The sealants are typically made from a combination of fibrinogen and thrombin with an added fibrinolysis inhibitor that stabilizes the resulting clot. When the fibrinogen and thrombin solutions are mixed, they become active, forming a clot or adhesive. A high thrombin concentration leads to more rapid clot formation, while a higher fibrinogen concentration induces a stronger meshwork. In a laparoscopic porcine heminephrectomy model without any parenchymal suturing, a powder spray formulation of lyophilized fibrinogen and thrombin prevented bleeding and urine leak [38].

Tisseel (Baxter, Glendale, CA, USA) is Food and Drug Administration (FDA) approved for hemostatic and adhesive uses, while CoStasis (Cohesion Technologies Inc, Palo Alto, CA, USA) is approved for hemostasis alone as it uses the patient's own plasma mixed with bovine thrombin and collagen. All fibrin products work best on a dry field in contrast to matrix agents which need the patient's own blood components to be activated. Despite the absence of any reported cases of viral transmission, this concern led to the development of products that use autologous blood to obtain thrombin and fibrinogen, such as Vitagel (Orthovita, Malvern, PA, USA) and CryoSeal (Thermogenesis, Rancho Cordova, CA, USA).

Matrix agents

Matrix hemostats have no adhesive properties but are excellent for hemostasis during active bleeding, as they require a bleeding source of fibrinogen [39]. FloSeal (Baxter, Deerfield, IL, USA) consists of cross-linked bovine collagen granules soaked in human thrombin. Upon contact with blood, the granules swell to provide a tamponade effect. The matrix is biocompatible and is reabsorbed in 8 weeks. Side effects are related to bovine allergy and potential for viral transmission. Another product is the EndoAvitene (Davol, Warwick, RI, USA), which is a preloaded endoscopic system that contains an active collagen that accelerates platelet aggregation and release of fibrin to form clot.

Chemical agents

Chemical sealants, as their name suggests, are used for tissue adhesion and not specifically for hemostasis, although adherence to vessels may physically seal them. BioGlue (CryoLife Inc, Kennesaw, GA, USA) is composed of bovine serum albumin (BSA) and glutaraldehyde. The latter compound cross-links the BSA molecules to the tissue protein, independent of the clotting cascade. Polymerization occurs within 30 s of application and maximal strength is achieved at 2 min. CoSeal (Baxter) is completely synthetic and has immediate capabilities, but must be applied in a dry field as must BioGlue. It is a polyethylene glycol hydrogel and is FDA approved for sealing vascular grafts [40]. Extensive swelling of CoSeal upon activation is a concern when applied in closed spaces.

Complications and limitations

The risks of fibrin products include viral transmission, anaphylaxis, and coagulopathy due to the use of homologous and bovine products. Human immunodeficiency virus (HIV), Epstein–Barr virus (EBV), cytomegalovirus (CMV), and hepatitis viral transmission due to the use of human samples is controlled by donor screening, thrombin nanofiltration, fibrinogen heat pasteurization, and solvent/detergent treatment [41, 42]. Anaphylaxis is rare and there is only one case report of allergy to aprotinin [43]. The use of products containing bovine proteins in patients known to have hypersensitivity to bovine products is contraindicated. There are no reported systemic effects of sealants, which potentially include systemic activation of the coagulation cascade and fatal thrombosis.

There is no perfect agent (Table 71.4). Fibrin products need a long preparation time, which makes them less useful in certain situations such as uncontrolled hemorrhage. Matrix hemostats have limited adhesive properties and need to be administered in a short period of time. Chemical sealants are prepared very fast but they are less absorbable than other components, not as useful for hemostasis, and require a dry field.

Suturing instruments

Difficulties with intracorporeal laparoscopic suturing are due to a fixed center of motion, limited needle and suture handling ability, lack of 3D perspective, and intracorporeal knot tying. Free-hand suturing is applicable to most situations and offers the greatest flexibility in needle, suture, and angle at which a needle may be held. Needle drivers can have a single action or a Castro–Viejo-type inline locking mechanism. Additional instruments have been developed to facilitate suturing.

The Endo Stitch (US Surgical) is an innovative device that passes a small needle with its secured suture back and forth between its jaws, allowing both running and interrupted suturing techniques without reloading the needle and facilitating rapid intracorporeal knot tying. Its limitations include its 10-mm width and short dull needle that cannot pass through thick tissue. As the

Table 71.4 Hemostatic agents and sealants.

Product	Class	Composition	Field	Limitations	Price (US$)*
Tisseel (Baxter)	Fibrin	Allogenic fibrinogen + thrombin Synthetic aprotinin	Dry	Viral transmission Preparation time 20 min	205 (4 mL)

**Cryoseal is not available in the USA.

device is disposable and needs proprietary reloads, it adds to the expenses of the case. The Endo Stitch has been used successfully in reconstructive cases, as in pyeloplasty [44].

The Suture Assist (Ethicon) is a 5-mm instrument designed to quickly place a pretied knot after using either the device or a needle driver to place a single or figure-of-eight throw. It is also disposable and uses dedicated reloads.

The Sew-Right SR5 (LSI Solutions, Rochester, NY, USA) uses two in-built needles to place a simple suture precisely through even relatively thick tissue. Advantages include its 5-mm size and needle passage parallel to the device. If the needle deviates or does not fully penetrate the tissue, it will not engage the suture at the distal jaw. It is disposable and allows only a single simple suture every load.

The Quick-Stitch (Pare Surgical, Englewood, CO, USA) is available in 3-, 5-, 10-, and 12-mm versions. It has a proprietary needle driver passed through a spool containing a pretied knot. A single or figure-of-eight suture is placed, followed by release, setting, and advancement of the knot. The device and needle driver are reusable, making it commercially appealing. Straight, curved, and blunt needles are available on absorbable and nonabsorbable suture.

Intracorporeal knot tying is a quick and versatile technique that may challenge novice laparoscopists. Knot tying is challenging, especially the second knot in a running suture, as there is only a short suture length available for tying, a single strand needs to be tied to a loop, and it is difficult to maintain constant tension on a knot. The Lapra-Ty (Ethicon Endo-Surgery) is an absorbable polydioxanone clip delivered by a reusable 10-mm device. The Lapra-Ty can be placed on the tail of a suture as the first knot or at the end of a running or simple suture instead of tying a knot. A concern is that a large number of clips may incite an inflammatory reaction. Therefore, it is better to use this device for the final "knot" of running sutures.

Another "knot-tying" device is the TiKnot TK5 (LSI Solutions). It is similar to extracorporeal knot tying using a titanium cylinder as a knot. Advantages promoted by the manufacturer include precise tensioning, one-step suture tying and cutting, and titanium's nonreactivity. Disadvantages are the need for extracorporeal loading of the suture into the device and the costs of a disposable instrument.

Tissue entrapment and retrieval instruments

There are various instruments available for tissue entrapment, depending on the size of tissue and whether or not an intact specimen needs to be retrieved. The Endocatch (US Surgical) is a self-opening bag that comes in several sizes, including 10 mm and 15 mm. The

Endopath (Ethicon) is available in the 10-mm size only. Once the instrument is passed into the cavity, the inner core handle slides forward, advancing the bag. A metal band automatically opens the bag and this is used to entrap the specimen. The bag is closed and torn away from the metallic ring when a separate string is pulled. Both bags are not strong enough for morcellation.

Morcellation requires a more robust impermeable bag that does not allow leakage of bacteria or tumor cells [45]. The LapSac (Cook Urological Inc, Spencer, IN, USA) is a double layer of plastic and nylon and is the most resistant to tearing [46]. There are some tricks that allow the bag to entrap large specimens. A stiff-wire is passed through the holes in the LapSac to create a rigid opening. The bag and wire are rolled up and inserted through an 11-mm trocar site after removing the trocar. Then the trocar is passed through the wire to maintain pneumoperitoneum. After the specimen is entrapped, the wire is pulled and the sac is brought out through the trocar site.

Morcellation

Morcellation is needed when there is no involved malignancy and incision is not required. Morcellation of malignant lesions is controversial, if not contraindicated [47, 48]. Morcellation is done after entrapping the specimen in an impermeable bag (see above). After removing the strings of the bag and the trocar, the area is draped to prevent contamination. The simplest and cheapest way is through manual fragmentation and extraction of large pieces using forceps and Kocher clamps, after expanding the fascial incision to about 20 mm. Morcellation should be done under endoscopic vision to verify the integrity of the bag. The use of India ink may help in the determination of margin and staging [49].

Instruments for closure

Port sites that are 10 mm or wider should be closed as the incidence of port-site hernia is as high as 3% [50]. Theoretically, newer dilating noncutting trocars do not require closure up to 12 mm, but many surgeons continue to close sites of 10 mm or wider in adults and of 5 mm in children. Open suture closure can be performed using S-retractors, Alice clamps, and a 0-0 suture, but can be difficult, especially in obese patients. Several instruments have been developed to simplify the procedure of suture passage through the fascia into the cavity under direct vision, followed by suture retrieval with a second pass through the opposite side of the fascia.

The Carter–Thomason Needle-Point Suture Passer (Inlet Medical Inc, Eden Prairie, MN, USA) and Berci Fascial Closure Device (Karl Storz GmbH & Co KG, Tuttlingen, Germany) are very commonly used instruments (Figure 71.14). The Carter–Thomason is now only available for purchase as a disposable instrument (CT Closure System; Cooper Surgical, Trumbull, CT, USA). The EndoClose (US Surgical) is a similar disposable device but is more difficult to use due to its lower rigidity.

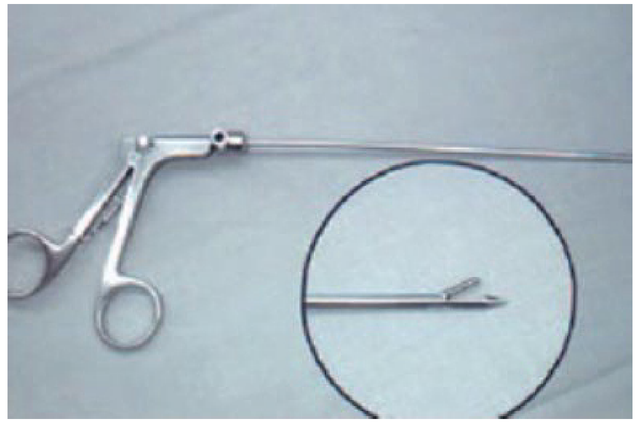

Figure 71.14 Berci fascial closure device (Karl Storz GmbH & Co KG, Tuttlingen, Germany) with tip close-up.

CHAPTER 72

Robotic Surgery: Basic Instrumentation and Troubleshooting

Wooju Jeong, Firas Petros & Craig Rogers
Vattikuti Urology Institute, Henry Ford Hospital, Detroit, MI, USA

The da Vinci System

The da Vinci Surgical System (Intuitive Surgical Inc, Sunnyvale, CA, USA) consists of three core components: a surgeon's console, a vision tower, and a patient cart with robotic arms. One arm controls the camera and the remaining two to three arms manipulate surgical instruments. The instruments have 7 degrees of freedom (DOF), including rotation, allowing for wristed, articulated movement. The surgeon sits at the console and is presented with a high-resolution three-dimensional (3D) view of the surgical field.

Surgeon's console (Figure 72.1)

The console is located in the same room as the patient. The console includes a stereo viewer with sensors as a safety mechanism. The system is activated when the surgeon's head is positioned in the console, and only then are the system arms allowed to move. If the surgeon's head is removed, deactivation occurs, and the robotic arms are locked in place.

The surgeon sits at the console with fingers inserted into two master controllers. The surgeon's hand movements are processed by compute engines and sent to the patient cart, which controls the robotic instruments inside the patient's body in realtime. With computer-assisted surgery, motion scaling can be performed to filter out physiologic tremor, allowing for finer movements [1].

Basic adjustments to the system, such as camera control, scope set-up, audio volume, and console height can be made while the surgeon is seated at the console. The console also allows the surgeon to toggle between the patient cart arms. All these tasks can be accomplished with the console's hand and foot pedal controls. The console is connected to the vision cart and patient cart components via cables.

Optical system

The da Vinci System offers 3D magnified vision. A binocular telescopic camera lens (0° or 30°) is attached to a high-resolution 3D high-definition (HD) camera (if HD System), and together they are held on the central robotic manipulator arm. The binocular images are translated by the computer into a magnified 3D image when viewed at the surgeon's console via the binocular viewport (Figure 72.2) [2]. The robotic scope is 12 mm in diameter and contains two 5-mm scopes. The images are cast on two different cathode ray tube (CRT) (LCD on Si Systems) screens and then synchronized to reflect the images of the CRT (LCD) to the binocular viewer in the console.

Patient cart (robotic arms and instruments; Figures 72.3 and 72.4)

The patient cart, consisting of the robotic arms and instruments, is positioned alongside the patient table [3]. The patient cart has either three or four arms, depending on the configuration of the system. Robotic

instruments have articulated joints (EndoWrist) near the tip that allow for wristed movement, providing 7 DOF of movement for surgical tasks such as suturing and dissection. Robotic instruments are available with a variety of instrument tips of 5- or 8-mm diameter.

The EndoWrist instruments are controlled by the surgeon at the console. The surgeon's finger, hand, and arm movements are translated into movements of the instrument tips. The foot pedals are used to toggle between instrument and camera movements, reset instrument movements (clutching), or initiate cautery [2]. If the robotic nondominant instrument is attached to cautery, care must be taken to avoid hitting the wrong foot pedal and causing thermal injury to the bowel or other structures [4].

Different instruments offer different relative advantages for different procedures. Commonly used EndoWrist instruments include: Hot Shears™ monopolar curved scissors, round-tipped scissors, ProGrasp™, fenestrated bipolar grasper, PK™ dissecting forceps, Maryland bipolar forceps, monopolar cautery hook, and needle drivers. In the nondominant hand, the broad smooth tips of the ProGrasp or fenestrated bipolar instruments can be used for atraumatic dissection of vessels. However, the fine sharp tips of the Maryland bipolar forceps or PK dissecting forceps can be used for precise cauterization of small vessels and dissection of structures. The ProGrasp has no thermal energy but has the strongest closing force, making it a robust grasping instrument. In the dominant hand, the Hot Shears can be used for tasks such as cauterization, blunt and sharp dissection, as well as for tumor excision in cases such as robot-assisted partial nephrectomy [4]. The monopolar

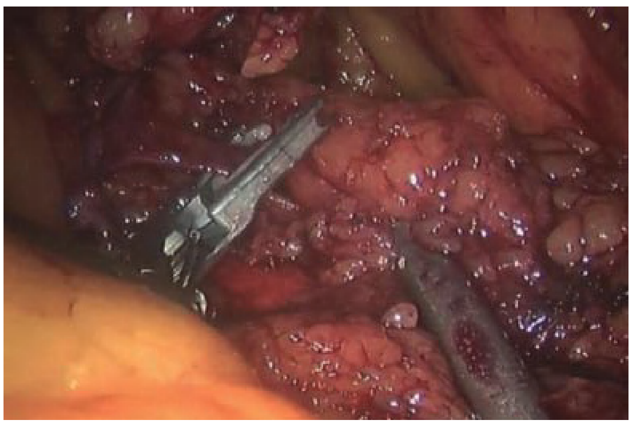

Figure 72.5 EndoWrist Hem-o-lok clip applier (© 2010 Intuitive Surgical Inc, Sunnyvale, CA, USA).

hook may be used for blunt dissection of vessels and dissection of tissue planes during extirpative procedures. Robotic ultrasonic shears are available but they lack EndoWrist capability [5].

Robotic needle drivers are available for suturing. The surgeon may choose to use a single EndoWrist needle driver in the dominant hand and keep an EndoWrist grasping instrument in the nondominant hand to economize instrument use. A SutureCut™ needle driver is also available that allows the console surgeon to cut sutures, but the needle tip is more bulky and care must be taken not to accidentally cut the suture while handling it during suturing.

The robotically enabled Hem-o-lok™ clip applier (Figure 72.5) can be useful for clipping vessels, particularly vessels at a challenging angle for the assistant to clip manually. The robotic Hem-o-lok clip applier holds a single 10-mm Hem-o-lok clip that is loaded externally and introduced by the assistant into the robotic port. Having a second robotic Hem-o-lok clip applier can facilitate faster exchanges. Care must be taken not to inadvertently squeeze the fingers as this may cause the clip to misfire. The robotic Hem-o-lok clip applier will accommodate 100 clip firings.

The life of most robotic instruments is 10 cases, after which the system will not allow the operational use of the instrument.

Third instrument arm

The third instrument arm can be utilized to provide retraction independent of the surgical assistant. The third instrument arm port is placed away from the other da Vinci instrument ports to minimize arm collisions. When using the third instrument arm for robot-assisted kidney surgery, a da Vinci S™ or Si™ Surgical System is preferred to avoid external collisions with the patient in the flank position. EndoWrist instruments used with the third instrument arm include the ProGrasp, dual blade retractor, and double fenestrated grasper (Figure 72.6). For robot-assisted kidney surgery, the third instrument arm can be used to lift the kidney anteriorly by placing it under the ureter [6]. This places the renal hilum on stretch, allowing two-handed dissection of hilar vessels. The dual blade retractor is long and has a broad surface area for atraumatic lifting of the kidney. The double fenestrated grasper is also long and may be used to grasp and retract structures. If arm collisions become a problem with the third instrument arm, it may be possible to switch instruments between the third instrument arm and the nearest working arm to minimize collisions.

TilePro multi-image display

TilePro is a multi-image video display mode of the da Vinci S and Si Surgical System that allows the surgeon

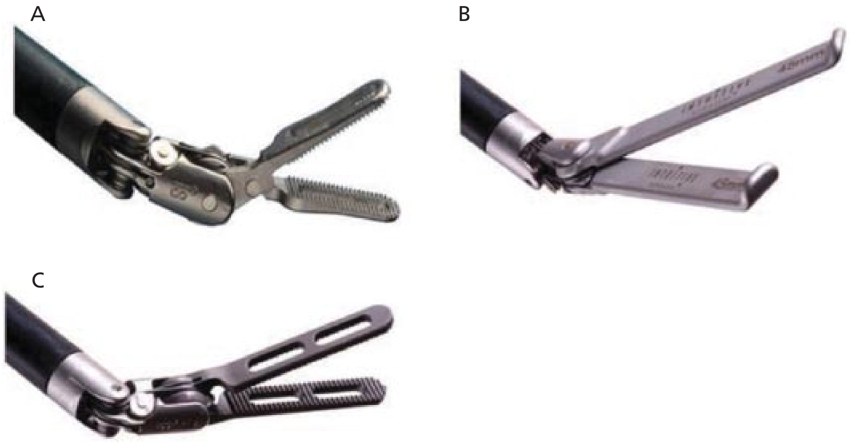

Figure 72.6 EndoWrist instruments with potential third instrument arm application. (A) ProGrasp; (B) dual blade retractor; (C) double fenestrated grasper. (courtesy of Intuitive Surgical Inc, Sunnyvale, CA, USA).

to simultaneously view up to two additional images, such as intraoperative ultrasound and preoperative computed tomography (CT) images, as a picture-on-picture on the 3D console screen and assistant monitors. TilePro can be used during robot-assisted partial nephrectomy to localize tumors and to delineate margins of resection using intraoperative ultrasound without the need to leave the console to view external images [6]. The surgeon can activate and switch back and forth from TilePro mode with a short tap on the camera pedal to turn the images on or off. The size of the image relative to the console view can be adjusted using the surgeon's console control panel. The TilePro images can be viewed on other monitors by the assistant and be recorded by the assistant selecting "Surgeon's view" on the touch screen monitor.

Dual console capability

An optional second console is available with the latest da Vinci Si System and allows two surgeons to collaborate during a procedure. Surgeons can exchange control of the instrument arms and endoscope using the surgeon touchpad, while an in-built intercom system facilitates communication. The addition of a second console offers an environment for training and provides a platform to refine techniques and learn new procedures.

Mechanical failure or malfunction and troubleshooting

Several studies have reported that the incidence of mechanical failure or malfunction with robot-assisted urologic surgery is low (0.4–4.6%) [5, 7–13]. Kim *et al*. reported the incidence of instrument and mechanical failures to be 1.9% [8]. Zorn *et al*. reported four cases of mechanical failure and completed all the cases by delaying the procedures [9]. In the series of Lavery *et al*., 34 cases had mechanical failures or malfunctions and were converted to an open or laparoscopic procedure, or were cancelled [10]. Dry lab experience to allow the surgical team to practice with the robotic instruments and the robotic interface is strongly recommended to learn to prevent and troubleshoot problems [14].

Robotic instrument problems include shaft injuries, broken or dislodged wires, nonrecognition or locking of instruments, or problems with engaging the instrument arm sterile adapter. Instrument failure can be fixed in most cases by reseating the instrument and sterile adaptor or changing to a new instrument. Careful examination of instruments should be undertaken by the table-side surgeon before insertion. If the instrument or sterile adaptor does not engage after replacing the instrument, the sterile adapter is replaced and it is confirmed that all disks spin and are spongy when pressed. If there are still problems with engagement, this should be reported to the Intuitive Surgical dVSTAT group using the Customer Service phone number.

Mechanical failures or malfunctions of the da Vinci System may include on/off failure, malfunctions of the console or optic system, and robotic arm malfunctions. In case of the system not powering on or malfunctions of the console or optic system, all AC power connections and circuit breakers should be checked. System cables should be carefully examined for debris or bent pins and reconnected. If the system is still not powering on or functioning appropriately, the problem should be reported to the Intuitive Surgical dVSTAT group.

If a robotic arm failure occurs, the arm can be disabled by using an option on the surgeon console touchpad and the vision cart touchscreen (da Vinci Si) or pressing and holding the HOME button (da Vinci S). The robotic arm can be moved out of the way by pressing the clutch on the instrument arm.

The da Vinci System will provide warning alarms indicating different faults, which include recoverable and nonrecoverable faults. Examples of recoverable faults include difficulty determining instrument arm position, excessive force on surgical arms, collisions between surgical arms, power fluctuation detected, and low battery back-up. These faults can be overridden by pressing the recover fault button on the surgeon's console touchpad or vision cart touchscreen monitor (Si), or the fault override button (S). If a nonrecoverable fault occurs, the instruments may need to be removed and the system shut down and restarted. Pressing the emergency stop button will stop system operation at any time. This is considered a recoverable fault and can be overridden in a similar fashion.

If a conversion to open or laparoscopic surgery is necessary, instruments and robotic arms from cannulas are manually removed and disconnected using the clutch on the robotic arms. In an emergency conversion, cannulas may be removed with the surgical arms.

CHAPTER 73

Minimally Invasive Urologic Reconstructive Techniques: Suture, Staple, and Clip Technology

Michael J. Schwartz
Hofstra University School of Medicine, Smith Institute for Urology, New Hyde Park, NY, USA

Introduction

Reconstructive techniques have long been an integral part of urologic surgery. Many common urologic procedures, in fact, rely on surgical reconstruction of the genitourinary system as a major component of the operation. Radical prostatectomy, pyeloplasty, partial nephrectomy, radical and partial cystectomy, ureteral reimplantation, and ureteral reconstructions are examples of common urologic procedures where reconstructive techniques are utilized. The foundations of these techniques lie in open surgery, where principles such as mucosal apposition, tension-free anastomoses, and maintenance of blood supply, have evolved to allow for the success of these surgeries for decades.

With the emergence of minimally invasive and laparoscopic procedures over the past 20 years, challenges arose to duplicate reconstructive techniques in the closed environment. The goal, of course, was to minimize patient morbidity while maintaining success rates. Initially, however, the tools to perform these surgeries were extremely limited, making laparoscopic reconstruction a daunting task for even the most experienced surgeons. The need to perform intracorporeal suturing was the most apparent limitation. However, with perseverance and time, laparoscopic techniques and instruments have evolved to allow these operations to be performed with a high degree of success, with results equivalent to those of open surgery. At the same time, hospital stay, complications, pain medication requirement, recovery period, and return to convalescence have all been markedly reduced [1, 2].

This chapter reviews many of the techniques and instrumentation used in urologic reconstructive laparoscopy. Techniques specific to individual procedures will be covered in the relevant chapters.

Basics of minimally invasive reconstruction

Hemostasis

Hemostasis is essential with any surgery, but it is of particular value when reconstruction is required. Inadequate control of even minimal bleeding can impair proper visualization of the area of interest, a critically important factor necessary for the precise placement of sutures [3]. Suturing in the closed environment is often a time-consuming task and getting things right the first time often gives the best chance for success. As every urologist knows, redoing an anastomosis is both traumatic to the involved tissues and potentially frustrating. Taking the additional time to ensure hemostasis prior to initiating intracorporeal suturing will optimize results.

There are a multitude of methods that can be applied in the laparoscopic environment to achieve hemostatic control, and these fall into several different categories (Table 73.1). First is the application of pressure. This can be achieved with the introduction of a small laparotomy pad into the abdomen for application of local pressure or,

if bleeding is more diffuse, the intracorporeal pressure can be briefly increased to aid in hemostatic control. Often, minor venous bleeding may be controlled simply by avoiding manipulation of the bleeding area and temporarily focusing attention on another aspect of the surgical field until physiologic clotting factors have taken effect. Localized bleeding from a distinct vessel may also be controlled with clips, clamps, sutures, or stapling devices. Thermal energy sources are another potential means to control localized bleeding. For example, argon beam coagulation is the initial method of choice to control bleeding arising from a splenic or liver laceration. Monopolar and bipolar cautery instruments are also widely available and may be used to control small vessels. Small vessel bleeding may also be controlled with ultrasonic energy. Suture ligation or repair may be necessary in some instances, such as laceration injuries to larger vascular structures. There is also a wide breadth of products on the market to promote hemostasis in the laparoscopic environment when other measures are inadequate or inappropriate (Table 73.2). If significant bleeding occurs that is not readily amenable to laparoscopic control and repair, open conversion becomes necessary [4].

Skill acquisition

The most important factor when approaching intracorporeal reconstruction is the surgeon's experience. There is no question that laparoscopic needle manipulation and placement, suturing, knot tying, and appropriate tissue handling are some of the most difficult surgical skills to master [5]. The learning curve is long and much of the instrument management can seem counterintuitive. While gaining laparoscopic experience with nonreconstructive techniques such as radical nephrectomy offers crucial skill acquisition in the closed operating environment, it has also been shown that laparoscopic surgical simulators may be helpful in moving up the learning curve more quickly [6–8]. This observation is especially relevant in residency training environments where learning and teaching opportunities are decreasing. Increasing financial and time constraints, pressure due to medicolegal concerns, and limited work hours all contribute to this trend. The importance of developing realistic virtual reality surgical simulators is brought to a new level in this context. While computer simulation in this realm remains limited to date due to difficulty in mimicking the properties of a large range of tissues and their responses to instrument manipulation, even low-fidelity simulators have been shown to offer advantage to surgeons training for laparoscopic surgery. Simple skills such as needle transfer and positioning, suturing, and knot tying can all be practiced and brought to a high level before even stepping into the operating room [9].

Laparoscopic suturing

Developing skill with laparoscopic suturing is probably one of the most daunting challenges in minimally invasive surgery. Frustrations can occur at almost any stage, from introduction of the suture material to the withdrawal of the needle. Seemingly simple tasks that are routine and taken for granted in open surgery, such as needle alignment, may be sources of frustration in the intracorporeal environment. Each step requires a more deliberate approach to avoid frustration and to attain successful results.

Needle passage

The first step in successful application of intracorporeal needle driving is safe introduction of the needle and suture material into the abdominal space through a trocar or directly through the anterior abdominal wall. Experience with a breadth of needle sizes and shapes is helpful in determining which needles can be safely and reliably passed through trocars of different diameters. Additionally, the surgeon must bear in mind that the valve mechanism important for maintaining pneumoperitoneum may be damaged with the passage of a needle. Grasping the suture approximately 1–2 cm proximal to the needle with a laparoscopic needle driver will facilitate passage of both the needle driver and the suture through the trocar, and minimize trauma to the valve by allowing the needle to pass through the path of least resistance. When using a 5-mm trocar with a 5-mm instrument, the internal diameter will not accommodate both a laparoscopic needle driver and needle side by side, and an alternative approach is required. The cut end of the suture is first passed through the trocar and handed off to a second needle driver placed through a second port. The first needle driver may then be withdrawn and the second driver is used to pull the remaining suture and needle through the trocar with the full internal diameter of the trocar available to

Table 73.2 Adjuvant hemostatic agents.

Agent	Product	Manufacturer	Mechanism	Preparation time	Advantages	Disadvantages	Approximate cost (US$)
Oxidized regenerated cellulose	Surgicel Fibrillar Nu-Knit	Johnson & Johnson Ethicon	Matrix for platelet plug formation, vasoconstriction	Off the shelf	Plant-derived Absorbs fluid Bactericidal (acidic environment) Lower cost	Less effective hemostat	12–92/packet
Collagen	Avitene Ultrafoam Instat	Davol Davol Johnson & Johnson	Matrix for platelet plug formation, vasoconstriction	Off the shelf	Plant-derived Available as sponge or powder	Not for use in closed environment Adhesion formation Cost	625/5 mL
Gelatin	Gelfoam Surgifoam	Pfizer/Baxter Johnson & Johnson	Mechanical effect and/or activation of clotting cascade	Off the shelf	Rapid hemostasis May be molded to tissue surface Lower cost	Contraindicated in infected field Risk of embolization	80–120 120
Flowable gelatin/thrombin	Floseal Surgiflo	Baxter Ethicon	Matrix for platelet plug formation, facilitates fibrin clot formation	3–5 min	Rapid hemostasis Precise application More tissue contact than gelatin sponge	Allergic potential (animal-derived thrombin) Cost	262/5 mL
Thrombin (bovine, human, recombinant human)	Thrombin Evithrom Recothrom	King Pharma Johnson & Johnson Zymogenetics	Converts fibrinogen to fibrin Clot stablization	3–5 min	Spray or drip Can be used in combination with gelatin sponges	Animal-derived thrombin may be immunogenic Cost	80/5 mL 95/5 mL 110/5 mL
Fibrin sealants	Tisseel (bovine)	Baxter	Promotes fibrin clot formation and inhibits fibrinolysis	15 min	Suture may be passed through sealant	Higher risk of immune reaction May impair wound healing if applied in thick layers Cost	220/4 mL
	Evicel (human)	Johnson & Johnson		1–3 min	Lower risk of immune reaction Suture may be passed through sealant	May impair wound healing if applied in thick layers Cost	340/4 mL
Synthetic sealants	Bioglue CoSeal	Cryolife Baxter	Binds covalently to tissue surface	1–3 min	Creates shell over applied area	Caution to remove instruments/needles prior to application Cannot suture through Cost	325/5 mL 630/4 mL

Figure 73.1 Valveless trocar system (SurgiQuest Inc, Orange, CT, USA). The system uses forced air to maintain a focal curtain of high pressure, preventing escape of gas from the abdomen.

accommodate the incoming needle. Direct grasping of the needle for passage is not typically recommended as it fixes the needle in place and may result in undue stress on the trocar valve.

Valveless trocars are now available that can provide advantage in passage of needles, clips, clamps, small specimens, or laparotomy pads in and out of the abdominal space (Figure 73.1). The lack of impedance facilitates passage through the device and, without the presence of a valve, the chances of dislodging a clip or compromising the pneumoperitoneum secondary to valve damage are dramatically reduced.

Straight needles may be passed in an out of the abdomen either through a trocar or directly through the abdominal wall. This technique is particularly useful when a stay suture is needed for placement of temporary traction on a structure during reconstruction (e.g. laparoscopic pyeloplasty). Floppy visceral structures such as the bladder or renal pelvis are examples as they may present a challenge when attempting precise suture placement. Use of a straight needle to place a stay suture in the target viscera can provide exposure and counter-traction. Placement of the suture directly through the abdominal wall, through the target tissue, and then back out through the abdominal wall allows the suture to be clamped outside the abdomen on appropriate traction. This technique may therefore obviate the need for an additional trocar for purposes of retraction, decreasing morbidity and freeing both the surgeon's hands for needle driving and suture tying. Traction can be easily adjusted as needed as the reconstruction proceeds.

Needle driving

Successful needle driving requires both correct needle and tissue alignment. After introducing a suture into the abdomen, two needle drivers are typically used to grasp and align the suture. The assisting instrument (most often the nondominant hand) grasps either the needle itself near the tip or the suture immediately adjacent to the needle. This facilitates needle manipulation until the desired alignment is achieved. When using a curved needle, positioning the driver halfway along the arc of the needle maximizes the level of control. Similarly, when using a straight needle, the positioning of the driver midway along the shaft of a straight needle provides the best level of control. Needle drivers themselves are available in several different configurations and may be used according to surgeon preference (Figure 73.2). Finding the most comfortable driver will often provide an additional level of control and aid in precise needle placement.

Once properly positioned, the assisting instrument helps to provide both proper tissue alignment and counter-traction during passage of the needle. It is important to fully engage the locking mechanism of the laparoscopic needle driver before passing the suture. Taking this step will help minimize unintentional needle deflections and increase the precision with which intracorporeal suturing can be performed. Zooming in with the laparoscope and taking advantage of the magnification it provides will further increase precision of suture placement. After passing the needle through the entrance site, the assisting instrument continues to provide counter-traction while the driver either further advances the needle or grasps it near the tip to complete the bite and exit the needle from the tissue.

Angles of a suture line or tissue position often require the surgeon to place sutures using a backhand technique or to use the nondominant hand for needle driving. It is critical for the surgeon to be comfortable with both of these methods as they can facilitate optimal suture placement and tissue reconstruction when applied appropriately. Also contributing to level of difficulty is the nonstatic nature of abdominal viscera that may move secondary to peristalsis or respiratory excursion.

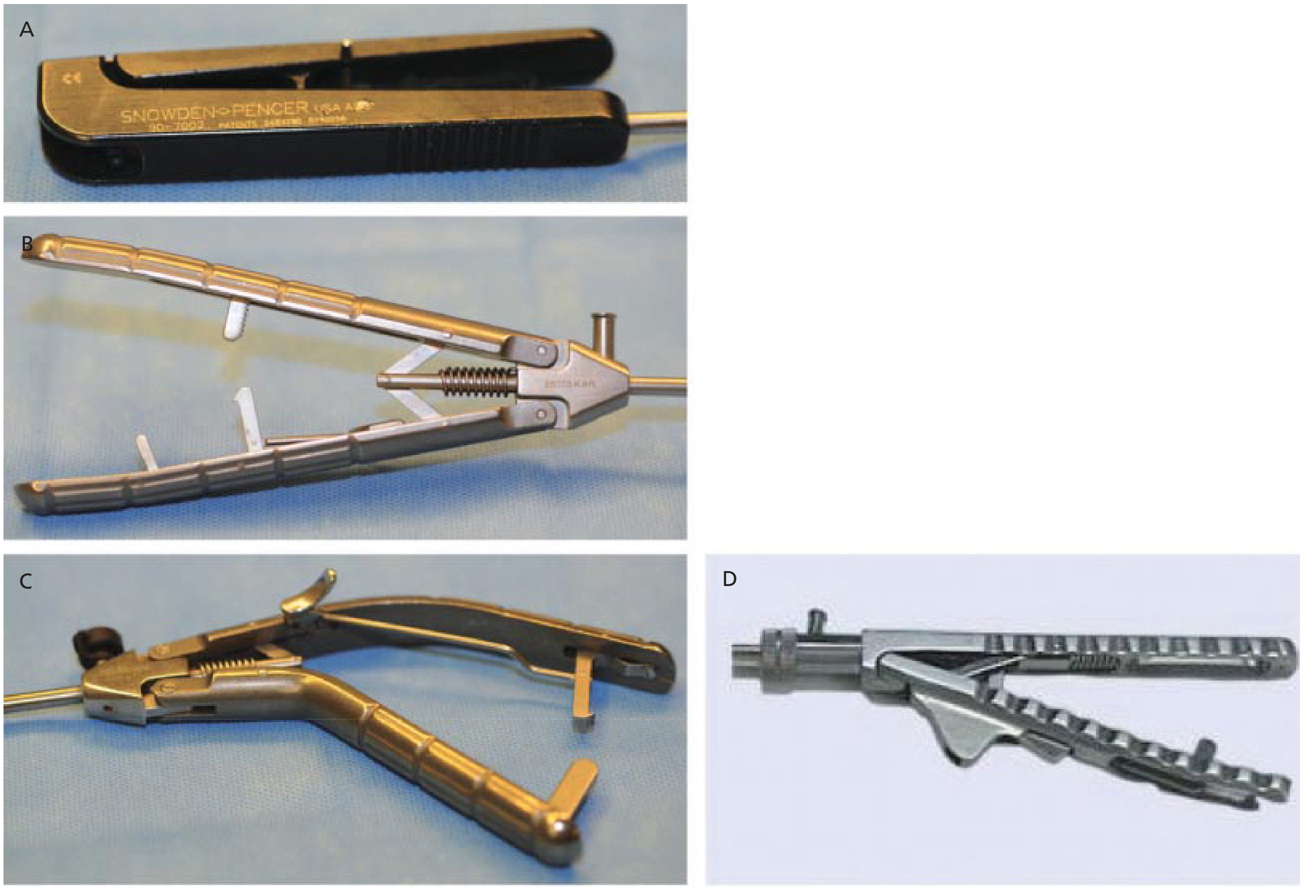

Figure 73.2 Handles available for laparoscopic needle drivers. Each has different locking and unlocking mechanisms. (A) Back-hinged needle driver (Snowder-Pencer Inc, Tucker, GA, USA). (B) Pistol and (C) palm grip needle drivers (Karl Storz, Tuttlingen, Germany). (D) Pistol grip needle driver (Ethicon, Cincinnati, OH, USA).

Methods to stabilize an area targeted for reconstruction include placement of stay sutures (as mentioned above), introduction of a laparotomy pad to bolster tissues, and accessory instruments for retraction.

Suturing

The principles of suture placement apply equally to both open and laparoscopic surgery. The primary goal in reconstructive cases is to achieve bites that equally appose each side of a suture line. Maintaining equal depth of entrance and exit sites on both sides of an anastomosis helps to avoid undue tension on one side or the other and reduces the chance of stricture. Similarly with renorrhaphy after partial nephrectomy, equal spacing and depth of needle entrance and exit sites helps avoid placing asymmetric tension on the kidney when cinching the suture. Undue tension can result in the suture pulling through the renal parenchyma, increasing both the complexity and time of the repair.

Urologic reconstruction utilizes a large breadth of techniques, suture material, size, and length, depending on both the procedure being performed and surgeon preference. The choice is often dictated by tissue thickness and texture. Simple interrupted sutures require the shortest suture length and typically 8–10 cm is adequate [10]. Running sutures require additional length that will vary with size of the defect to be closed or the circumference of the anastomosis. Approximately 10–12 mm of additional suture length is needed for each additional throw of the suture. Running locking sutures require significant additional length, with 20–25 mm needed per stitch. With larger closures, this may result in a cumbersome length of intracorporeal suture that can complicate or prolong the reconstruction. In these cases, separate sutures are recommended to facilitate the process. Adequate length should be maintained for knot tying at the conclusion of suturing such that manipulation of the suture for tying does not place stress on the reconstructed tissue.

An additional method of intracorporeal suturing involves the use of purpose-built instruments that automatically grasp, drive, and regrasp the needle. The Endo Stitch (Autosuture, US Surgical, Norwalk, CT, USA) is such a device that allows for suturing with a single instrument rather than two separate needle drivers. In order to suture, the needle with attached suture is transferred back and forth between the two arms in a side-to-side fashion at the tip of the instrument. After each pass, the needle is temporarily locked in place until the instrument handle is squeezed again to transfer it to the other arm. Its diameter requires a 10-mm port and it is best suited for reconstruction of thin visceral structures, such as the renal pelvis during pyeloplasty or bladder during ureteral reimplant. The small needle size used with the Endo Stitch device prohibits its use for reconstruction requiring larger bites, such as renorrhaphy.

There are also 5-mm instruments available for intracorporeal suturing using a mechanism that passes the suture in a direction parallel to the instrument shaft. The Sew-Right device (LSI Solutions, Victor, NY, USA) incorporates a notch near the tip of the instrument to accommodate the target tissue (Figure 73.3). A needle can then be passed forward through the tissue, locking into the suture at the distal end of the instrument. The suture is then brought back through the tissue to complete the "driving" of the suture. Engaging the handle again will reset the suture at the distal end of the instrument to prepare for the next pass. Once the suture is complete, the instrument is disengaged from the suture and a separate purpose-built instrument is used to pass titanium knots onto the suture, securing it in place.

Knot tying

Suturing in laparoscopic surgery can involve either intracorporeal or extracorporeal techniques. The basic principles broadly overlap and familiarity with each may be useful for various applications.

Extracorporeal techniques

Most commonly, extracorporeal knot tying is used for fascial closure of trocar entry points. There are numerous devices that may be used to assist in suture passage through the fascia from extra- to intra-corporeal space and back under visual guidance from the laparoscope. This technique is particularly useful in obese patients where pure extracorporeal fascial closure can present an extremely difficult challenge without significant enlargement of the skin incision. With a sling suture technique and extracorporeal knotting, the fascia may be closed while preserving the minimally invasive nature of the surgery.

The simplest and most ubiquitous extracorporeal knot is the square knot. This may be used in combination with intracorporeal suturing by maintaining a long suture length (80–120 cm) and using a knot pusher. With

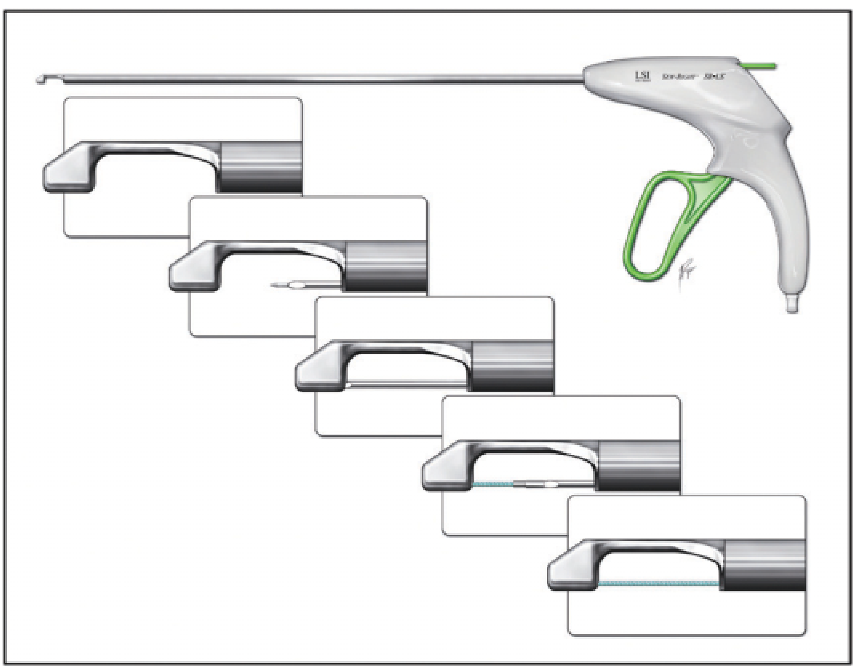

Figure 73.3 Sew-Right device (LSI Solutions, Victor, NY, USA) provides an automatic suture passing mechanism in a direction parallel to the 5-mm instrument shaft (courtesy of LSI Solutions).

the tail of the suture clamped outside of the trocar, the needle may be brought back through the trocar after suture placement in the target tissue. Alternating half hitches may then be formed, with the knot pusher being used to cinch each throw down to the tissue. Placing a surgeon's knot as the first throw will help maintain tension locally at the level of the tissue while the subsequent hitch is formed extracorporeally. Tension is maintained on the free ends of the suture with one hand while advancing the knot pusher with the other.

The Roeder slip knot may also be employed during laparoscopic suturing or loop ligation. It holds the advantage of being entirely formed before advancing it into the intracorporeal space. The slip feature may be particularly useful if the target tissue for ligation is somewhat bulky (e.g. the dorsal venous complex during laparoscopic radical prostatectomy) or if the target tissue is under tension. With a single throw required, the risk of an air knot is minimized. Once the initial knot is in position, additional half hitches may be placed for security. To form the knot, a half hitch is placed approximately 6 inches above the level of the trocar mouth. With the hitch pinched between the thumb and a finger, the free end is then looped around the two strands. The number of loops is dependent on the suture material used; monofilaments require five to seven loops while braided and gut-based sutures require three to five passes. Finally, the knot is completed by passing the free end of the suture between the two strands and cinching tight. Alternatively, the free end may be wrapped around one of the strands and then brought back up through the first loop formed below the half hitch. In either case, a knot pusher is used to advance the knot to the tissue while maintaining tension on the two strands.

The primary disadvantages of extracorporeal suturing include potential loss of pneumoperitoneum through the internal lumen of the knot pusher, lack of continuous control of the suture locally at the tissue level, maintenance of long suture material length, and placement of undue tension on the target tissue while cinching knots.

Intracorporeal techniques

Intracorporeal knot tying can be one of the more time-consuming parts of laparoscopic reconstructive surgery. Multiple factors in the intracorporeal environment can contribute to the level of difficulty. Sutures may stick to abdominal viscera due to water tension, making it difficult to locate a free end after needle passage. In some instances, more than one suture will be placed for reconstruction prior to tying, making it more challenging to locate the correct suture when knotting is initiated. Use of brightly and various colored suture material may aid in knot tying when more than one suture is required.

Similar to the practice of instrument tying in the open environment, it is recommended to leave a relatively short tail prior to tying a knot. A long tail may make it more difficult to locate the terminal end of the suture and will undoubtedly require additional cinching movements to bring the knot down to the target tissue. Furthermore, if placing a running suture, a lengthy tail will unnecessarily reduce suture length and make tying a knot at the opposite end of the suture line potentially more difficult.

The square knot is the most commonly used intracorporeal knot tying technique. It is also extremely useful to learn to convert a square knot to a sliding knot if the target tissue is under any tension. In order to accomplish this task, two half hitches should be placed in the suture, but neither should be cinched down to the tissue. Instead, the free end of the suture should be grasped and placed on tension. This motion will convert the square to a slip knot, and with the free end still on tension, the knots may be pushed into place with the free instrument. Additional half hitches may then be thrown to properly secure the knot.

Aside from its purpose as a needle driver, the Endo Stitch device may also be used in a knot-tying capacity. Using a grasper to hold the free end of the suture, the length of the suture is brought between the jaws of the device. Passing the needle between the jaws, looping the free end of the suture, then passing the needle back to the original jaw will form a half hitch. The process can be repeated to form a square knot.

Suture anchors

As an alternative to knot tying, suture anchors may be used to secure both running or interrupted sutures. When a suture is complete, it is placed on the desired level of tension and an absorbable clip may be placed *in lieu* of a knot using the Lapra-Ty clip applier (Ethicon, Cincinnati, OH, USA). This device requires a 10-mm port and is nondisposable. It can be especially useful if the length of suture left at the end of a suture line is inadequate to easily tie a knot. These suture anchors may also be useful to reduce the time required to complete time-sensitive tasks such as renorrhaphy. By placing a Lapra-Ty clip at the free end of the suture prior to introducing it into the abdominal space, both sides of the suture material may be secured in this manner.

As mentioned above, titanium knots may also be used to secure a suture. This can be accomplished using a purpose-built instrument such as the Ti-Knot device (LSI Solutions). Both ends of the suture must be maintained at a length to allow the instrument to be loaded onto the two suture ends extracorporeally. Once loaded, the device is passed into the intracorporeal space, the

desired tension is achieved, and a titanium knot is deployed, which locks the suture in place.

Surgical clips

Laparoscopic clip appliers are readily available and routinely used for many laparoscopic procedures requiring the ligation of small veins, arteries or lymphatics. There are two main categories of clip materials used in the laparoscopic environment: titanium and nonabsorbable polymer (e.g. Hem-o-lok).

Instrumentation and application of titanium clips

Titanium clips are available in both straight and right-angled variations and are typically disposable, multiple load, single-use devices carrying between 15 and 30 clips per instrument. The advantages of these devices lie in their ability to allow for rapid application of multiple clips without the need to pass the instrument in and out of a trocar. This both decreases the time involved in vessel ligation and eliminates the potential for dislodging a clip on pass-through of the trocar valve. Closure of the clips occurs from distal to proximal, which helps prevent the desired vessel from being pushed forward and out of the apposing arms of the engaging clip as the jaws close. The titanium clips themselves are also typically textured along the internal surface with ridges and depressions to decrease the likelihood of becoming dislodged due to either subsequent dissection following ligation or arterial pressure within the ligated vessel.

Titanium clip appliers have several other features to facilitate their use. A rotational capability of 360° allows for ergonomic hand positioning, translating into ease of use and improved accuracy of clip placement. Some clip appliers also reload clips through an automatic mechanism, eliminating a step in the application of multiple clips in rapid succession. Some appliers slide a new clip into position immediately without requiring any action on the part of the surgeon; others require partial closure of the firing handle or have a separate trigger that reloads a clip when depressed. If the clip applier is to be used as a dissecting instrument in any capacity, the surgeon may elect to use an applier without the automatic reload feature to avoid dislodging the loaded clip during dissection. To avoid inadvertently traumatizing a blood vessel or other structure, most clip appliers are equipped with a safety mechanism preventing closure of the jaws unless a clip has been loaded into place. Most appliers now also incorporate a visual indicator to show the operating room staff if the number of remaining clips is low.

Principles of laparoscopic clip application for vessel ligation follow those of open surgery. First, there must be adequate dissection of the target vessel to both isolate it from surrounding structures and to develop space to place clips, leaving a gap between them and allowing for easy division with laparoscopic shears. A right-angled dissector or other dissecting forceps can be useful for this purpose. Once that is completed, the clip applier should be placed around the vessel and then slid up or down the vessel into optimal position before firing. Care should be taken during withdrawal of the applier as the applied clip may be pulled back and out of position if undue traction is inadvertently transferred to the clip. If a clip is misplaced, Maryland or DeBakey forceps may be used to slowly remove it by backing it straight off the clipped vessel or tissue.

Titanium clips may be used to clip vessels of any size, although most commonly they are applied to small-to-moderate sized structures. If a stapler cannot be applied or is not available, multiple titanium clips may be used as an alternative to clip vessels as large as the main renal artery during laparoscopic nephrectomy. The application of between three to five clips on the proximal side of the renal artery is necessary prior to division (Figure 73.4). For smaller vessels, typically one to two clips are used on both the proximal and distal sides of the area to be divided.

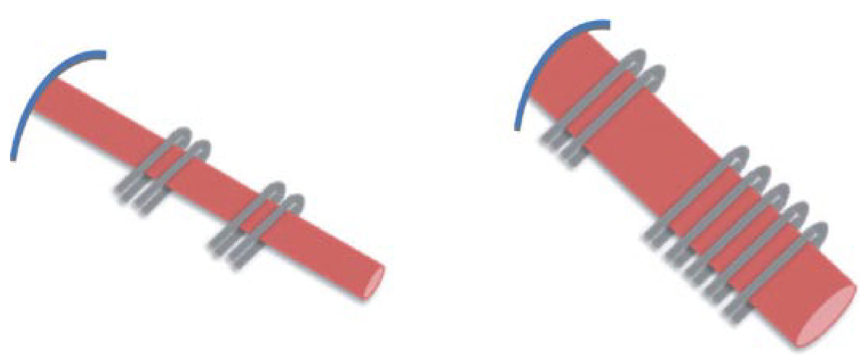

Figure 73.4 Clip ligation of small and large arteries. When using titanium clips to ligate larger vessels, such as the main renal artery, three to five clips should be used on the proximal side prior to division (courtesy of SurgiQuest Inc.).

Nonabsorbable polymer clips

Nonabsorbable polymer clips, more commonly known as Hem-o-lok clips or Weck clips (Weck Teleflex Medical, Research Triangle Park, NC, USA), can also be used for vessel ligation in the laparoscopic environment. These clips incorporate a locking mechanism such that the tips of the two arms can engage and lock through multiple tissue layers. This mechanism provides tactile feedback such that the surgeon can sense if the clip has properly engaged by feeling the transmitted clip closure through the laparoscopic applier. The advantage of this system lies in the security of the clip placement once engaged; they are quite cumbersome to dislodge even when intentionally trying to remove them. Even with the use of a purpose-built Hem-o-lok clip remover that helps disengage the locking mechanism, clip removal can be a challenge. After a clip has been placed and before withdrawing the applier, it is critical to ensure that the clip does not catch on the loading mechanism to avoid placing undue shear force on the target vessel. Similar to the titanium clip appliers, the Hem-o-lok clip appliers also have 360° rotational ability. Because the Hem-o-lok clip appliers are not multiple-load devices, the instrument must be removed and reloaded for each clip application. This occasionally leads to a clip becoming dislodged when passing into a trocar or through the abdominal cavity.

Linear surgical staplers

Laparoscopic stapling devices can be used for a multitude of purposes. In urologic procedures, they are primarily used for vessel ligation and division or reapproximation of visceral structures. They allow for rapid ligation with or without division of tissues by deploying several parallel rows of metallic staples laid in a brick-like intercalated pattern to allow overlap from one row to the next. Cutting devices typically use two sets of three parallel rows of staples and divide the ligated tissue between them. Noncutting staplers use fewer rows (three or four) of staples. Different lengths (30, 45, and 60 mm) and load types (vascular or thin loads, medium, and large) are also available (Figure 73.5). As their name suggests, vascular loads are ideal for ligation of vascular pedicles, such as the renal hilum during nephrectomy or bladder pedicles during cystectomy. The medium and large loads are useful for securing thicker structures such as bladder or bowel. All staplers offer 360° rotation and many are available with either a straight or articulating head. The articulating head can offer a greater range of motion and diversity in angle of application from a fixed trocar site. The downside is that articulating staplers come at a higher cost.

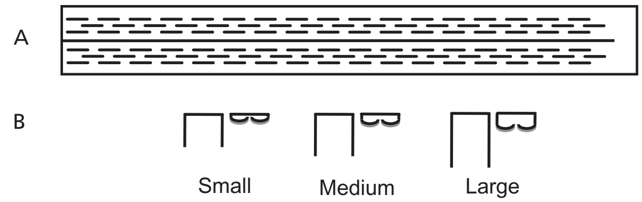

Figure 73.5 (A) Linear cutting stapler load showing configuration on the intercalated staples in two sets of three rows. After the stapler is fired, a blade cuts between the two sets of staples to divide the ligated tissue. (B) Individual staples of various sizes shown in both the open and closed position.

Before using a laparoscopic stapling device, several factors must be taken into consideration. First, most staplers require a 12-mm port size in order to be safely passed into the abdomen, and the jaws should be closed when introducing and withdrawing the instrument. This prevents inadvertent trocar dislodgement while passing the instrument. To avoid premature deployment of the staples or cutting blade, all stapling devices incorporate a safety mechanism that must be disengaged prior to firing. The target tissue must also be appropriately dissected free of surrounding connective tissue, of suitable thickness, and accessible to allow the arms of the staplers to be placed accurately, with tips visible, and closed without requiring undue pressure. If the target pedicle is too thick and the jaws do not close easily, there is a risk of incomplete ligation and subsequent bleeding. Reports of stapler misfire have appeared in the literature with a malfunction incidence of approximately 1.7% [11]. However, many of these complications were attributed to misuse of the device rather than equipment failure. The surgeon must always be prepared for this rare complication to avoid excessive blood loss or conversion to an open surgical approach. To minimize the risk of stapler misfire, some groups advocate the use of a noncutting stapler such as the endoscopic TA device. Once vessel ligation is verified, the target pedicle can then be divided. While this approach adds an additional step, it adds very little time to the overall operation. When using a stapler, it is also very important not to place any torque on the device as it is being fired. Doing so may result in either incomplete ligation or avulsion of the target vessel as the staples are fired. After firing the device, the jaws should be reopened prior to withdrawing the device from the target area, and the staple line can be inspected to ensure an intact ligation and hemostasis. In some instances, an additional reload may be required to complete the pedicle ligation. The jaws of the reload may be closed to incorporate and overlap the original staple line if necessary without compromising the ability of the device to fire and cut. However, it is critical to avoid inclusion of

a previously placed titanium clip into the jaws of the stapler as this will compromise both the staple deployment and cutting mechanism. Minimizing the number of clips in an area where the use of a laparoscopic stapler can be anticipated (such as the renal hilum) will lessen the chance of encountering difficulty with clips when maneuvering the stapler into position.

Future directions

The tools for laparoscopic reconstruction have improved dramatically over the past 20 years and will surely continue to become increasingly ergonomic and refined with time. While robotic surgery has introduced wristed instruments into the minimally invasive arena, these tools are also beginning to be used more frequently in the pure laparoscopic environment. Single-site surgery has demonstrated the potential of intracorporeal triangulation and may be another step on the path toward further reduction of surgical morbidity. Improving articulating instrumentation will undoubtedly continue to expand the realm of what is feasible, reproducible, and accessible in the laparoscopic environment.

CHAPTER 74

Obtaining Access: Transperitoneal Approach and Trocar Placement

Debora K. Moore, John C. Coleman & Robert G. Moore
Veterans Administration Medical Center, LSU Health Science Center, Shreveport, LA, USA

Introduction

Laparoscopic urologic surgery has evolved from an academic practice in the 1990s to one which transcends all forms of urologic practice. All successful urologic laparoscopy starts with the establishment of pneumoperitoneum, followed by primary and secondary trocar placement. Number, size, and arrangement of secondary trocars depend on the type of procedure, patient's body habitus, previous surgical procedures, and the surgeon's individual preference. This chapter will address techniques for both closed and open peritoneal access, anterior abdominal wall anatomy, general considerations, technique, and rationale for secondary trocar configuration and complications.

Anterior abdominal wall anatomy

A thorough knowledge of the anterior abdominal wall anatomy is essential for secondary trocar placement. This will decrease the possibility of vascular injury, hernia formation, or loss of access. The abdominal wall muscles are organized into two separate groups: anterolateral and posterior. The quadratus lumborum is the sole muscle in the posterior group [1]. The anterolateral group of abdominal muscles is divided into two subgroups based on the orientation of the muscle fibers. The rectus abdominis and pyramidalis are the two vertical muscles of the anterolateral abdominal group. The external abdominal oblique, internal abdominal oblique, and transversus abdominis muscles are three thin muscular layers that alternate in their fiber direction. The linea alba is a midline fusion of the aponeurosis of both the external and internal oblique that runs from the xiphoid process to the symphysis pubis. The linea alba is devoid of muscle and is ideal for placement of the primary and secondary trocars.

Blood vessels of the anterolateral abdominal wall that can affect laparoscopic port placement are divided into two groups: superficial or cutaneous and deep [1]. Superficial vessels include the superficial epigastric vessels (Figure 74.1). The superficial epigastric artery originates from the femoral artery just below the inguinal ligament. This artery traverses the femoral sheath to course toward the umbilicus in the subcutaneous tissue. Avoidance of these vessels and their branches is possible by transilluminating the abdominal wall.

The deep anterolateral abdominal wall vessels that influence laparoscopic port placement include: the superior and inferior epigastric vessels, intercostal vessels, subcostal vessels, and ascending branch of the deep circumflex iliac vessels [1] (Figure 74.2). The superior epigastric artery is the termination of the internal thoracic artery and courses downward posterior to the rectus abdominis muscle in the rectus sheath. The inferior epigastric artery originates from the external iliac artery just medial to the deep inguinal ring (lateral to the medial umbilical ligament). The inferior epigastric vessel courses toward the umbilicus and traverses the transversalis fascia at the arcuate line to ascend in the rectus sheath posterior to the rectus muscle. Both the superior and inferior epigastric vessels anastomose near

the umbilicus. Both vessels supply numerous branches to the rectus muscle and umbilicus. These vessels are often not seen on transillumination of the abdominal wall and for this reason, trocar placement through the rectus abdominis muscle should be avoided.

Intercostal vessels (X and XI) and the subcostal vessels traverse the lateral abdominal muscles, coursing in an oblique diagonal fashion from lateral to medial (midline) [1] (Figure 74.2). The ascending branch of the deep circumflex iliac artery originates near the anterior superior spine and ascends toward the costal margin. These vessels are generally not visualized during transillumination of the abdominal wall.

General considerations

While ablative laparoscopic urologic procedures have led the way in the development of minimally invasive urologic procedures, reconstructive urologic procedures are currently mainstream. Most reconstructive procedures are technically more difficult due to the laparoscopic suturing. While few studies exist on standardization of laparoscopic intracorporeal suturing and knot-tying techniques, it is known is that the positioning or placement of the ports plays a crucial role.

Trocar configuration and placement should be well thought out ahead of the procedure to maximize the utility of each individual cannula. Several basic tenets for trocar placement are useful.

Trocars should be placed within the operative field so that the sheath is pointing toward the operative field. Placing the ports in such a manner minimizes resistance when manipulating instruments. Placement of cannulas pointing away from the area of dissection can result in decreased maneuverability and tactile feedback transmitted through the instruments. The force needed to redirect the sheath can cause a tear in the peritonotomy and result in subcutaneous air. Subcutaneous air leads to leakage of gas at the port site, difficulty keeping the trocar in place, and increased gas absorption. The former events turn a simple laparoscopic case into a major struggle.

Another known fact is that secondary trocars must be adequately spaced so that external interlocking of laparoscopic instrument handles and internal overlapping of cannulas and laparoscopic instruments will not hamper surgeon maneuverability. For the novice, prior to secondary trocar placement, individual trocar sites can be mapped with a surgical marker pen after insufflation to ensure adequate working distance between the trocars.

If anterior abdominal trocars are to be used, they should be placed in either the midline or lateral to the rectus muscle to avoid the epigastric vessels and branches. In addition, trocars should be placed away from bony structures since these limit mobility. When the planned procedure requires a dorsal lithotomy or split frog-leg position, lower, laterally placed trocars may pose difficulties. Placement of a secondary trocar at the midline suprapubic area will allow greater trocar movement in these specific cases.

Frede *et al.* have described other special considerations given to secondary trocar configurations for laparoscopic reconstructive procedures in which laparoscopic suturing is needed [2]. They discuss three general rules to optimize laparoscopic suturing. First and foremost, rule 1is that "an isosceles triangle trocar instrument arrangement is needed for optimal suturing." Rule 2 dictates that the angle between laparoscopic instruments be adjusted between 25° and 45°. Rule 3 states that the angle between the horizontal plane and instruments should be kept at less than 55°. According to the authors, by using the above general principals, suturing time was decreased by 75% [2].

Choice of trocar size will vary depending on the size of instruments needed to perform the desired procedure. Routinely used trocars vary in width from 5 to 12 mm. Larger trocars are available for insertion of larger instruments (i.e. specialized bowel/vascular staplers and larger entrapment devices) and passage of suture material. In most instances, one of the secondary trocars should be a 10/12-mm cannula to accommodate larger instruments (clip applicators, tissue removal forceps, etc.). The standard trocar length is 10 cm; extra-long trocars (15 cm) are often used in obese patients. For flank/renal laparoscopic procedures in the obese patient, the whole trocar configuration is moved laterally to assure that laparoscopic instruments will be long enough to reach the field.

Access to the peritoneal cavity

The initial step of laparoscopy is to establish a pneumoperitoneum via an open or closed technique. In inexperienced hands, relative contraindications to pneumoperitoneum are prior abdominal surgery, nonreversible coagulopathy, and severe cardiopulmonary disease. However, several series of transperitoneal laparoscopic procedures in patients with prior surgical procedures have been successfully performed [3].

The closed technique for initiating a pneumoperitoneum is most commonly obtained via direct infusion of CO_2 into the peritoneal cavity through a Veress access needle. The Veress needle (Covidien, Norwalk, CT, USA) is a 14G needle which comes in standard and baratric lengths (Figure 74.3). This needle is made up of

an internal spring-loaded blunt-tip stylet surrounded by a sharper outer needle. This design protects intra-abdominal structures via the advancement of the inner sheath after the outer stealth encounters an area of decreased resistance (peritoneal cavity). The most common insufflation site is the umbilicus for pelvic cases and the mid-clavicular line for renal case. The primary advantage of the umbilical route for establishing pneumoperitoneum is the absence of intra-abdominal muscle at this site, so that the needle passes directly through the fused anterior and posterior rectus sheaths. Pneumoperitoneum for renal/adrenal procedures is initiated in the mid-clavicular line above the level of the anterior superior iliac crest. The Veress needle is inserted perpendicular to the fascial surface and the abdominal wall is tented upward with the nondominant hand. Two areas of maximum resistance are encountered as the needle passes through the abdominal wall fascia layers. Tactile feedback is key as the Veress needle passes into the peritoneal cavity (feeling the "two pops" are standard teaching points). Needle advancement is stopped. Correct placement of the needle into the peritoneal cavity is verified by the three tests [3]:

- No resistance when moving the needle tip;
- Saline irrigation and aspiration ("drop test") is preformed without entericus, blood, or air on gentle aspiration;
- Low opening pressures (<8 mmHg) at low flow rates.

It should be noted that obese patients will have higher opening pressures (close to 10 mmHg) secondary to the increased thickness of the abdominal wall and chest wall fat. Due to the extra weight on the abdominal/chest wall, the intra-abdominal pressure will stay at this level until the abdominal cavity reaches capacity (4–6 L).

Occasionally, when the above signs cannot be adequately demonstrated, the surgeon needs to troubleshoot. If the abdominal wall does not demonstrate symmetrical rise, either preperitoneal insufflation is taking place or abdominal hollow structures (i.e. colon or small bowel) are being insufflated. If the latter is suspected, the initial Veress needle should be left and another Veress needle should be placed in a different area. Once access has been obtained and the initial trocar is placed, the initial Veress needle is inspected under direct vision. If it is placed in a hollow viscus, it is at this time removed and necessary repairs are made. Another problem encountered is omental or mesentry insuffla-

tions. In this case placement testing appears normal; however, intra-abdominal pressures appear abnormally high or the occlusion alarm sounds. If suspected, the needle should be slowly pulled back and the tip angled upward while keeping an eye on the intra-abdominal pressure after each movement. If pressures do not drop below 8 mmHg, the Veress needle should be withdrawn and reinserted.

With successful establishment of the pneumoperitoneum, the intra-abdominal pressure is increased to 15–20 mmHg. Initial trocar placement is performed with two different techniques: utilizing a blind or visual trocar system. When a blind technique is utilized, either a fascial cutting or fascial splitting trocar is inserted through the abdominal wall with a twisting motion. Alternatively, the initial trocar can be placed via a radially expanding trocar system, which requires the use of a Veress needle which is back loaded with an expandable mesh sleeve prior to insertion. The dilating trocar is placed intra-abdominally by removing the Veress needle but leaving the mesh in place. A blunt-tipped trocar is placed through the mesh with the dominant hand while holding the mesh with the nondominant hand (Figure 74.4). Intraperitoneal trocar placement is confirmed by leakage of CO_2 out of the open side port. Direct videoendoscopic inspection is then preformed to verify intraperitoneal trocar placement and to exclude injury to intraperitoneal structures. Initial closed blind trocar placement is associated with increased risk of injury to intra-abdominal structures when compared to closed visual or open trocar placement [3–5].

Open trocar placement is potentially a safer way of gaining intraperitoneal access in patients with increased risk of intra-abdominal adhesions and scarring. The risk and severity of adhesions is much higher for prior open procedures when compared to the same laparoscopic procedure (66% vs 10%) and for patients with a history of gross spillage of bowel contents and foreign bodies (talc, shunts, peritoneal dialysis catheter, etc.) [3]. However, many experienced laparoscopist have obtained initial access via closed technique and have subsequently performed transperitoneal procedures in these patients [3].

Open (Hasson) technique

The technique to obtain open access for intraperitoneal insufflation is performed by making a 2-cm incision at the desired initial trocar site. With blunt dissection the anterior fascia is exposed with narrow retractors. The anterior fascial layer is incised and stay sutures of 2-0 Vicryl (polyglactin) are placed on either side of the fascia with the aid of a semi-circular needle (UR-5 or UR-6). The underlying structures are bluntly dissected to expose the posterior fascial layer, which is also incised, and the above stay sutures are placed on each side. The peritoneum is exposed, tented up, and incised. A blunt-tipped trocar (Hasson) is placed through the peritoneotomy and the stay sutures secured to the suture guides, holding the cannula in place via an attached circular cuff that prevents leakage of CO_2 (Figure 74.5). Alternatively, a cannula can be back-loaded on a 0° laparoscopic lens to "look your way into the peritoneal cavity." This modification allows the surgeon to immediately confirm correct placement. The open technique's major draw back is leakage of the pneumoperitoneum around the initial trocar. The surgeon should also be aware that this technique is extremely difficult in obese patients.

Hand-assisted access

Hand-assisted laparoscopic surgery requires a primary access site for the hand to assist with videoendoscopic renal surgery. The initial hand-assisted device, Pneumo-Sleeve (Weck Closure Systems, Research Triangle Park, NC, USA) required preinsufflation of the peritoneum

for proper placement of the device on the abdominal skin with adhesives. Subsequent hand-assisted devices have inner and outer abdominal rings attached to a wound protector. Pneumoperitoneum is maintained by various modifications of the hand-assisted device: (1) occlusive gel matrix (GelPort; Applied Medical, Rancho Santo Margarita, CA, USA; (2) twisted pneumatic cuff (OmniPort; Weck Closure Systems, Research Triangle Park, NC, USA), and adjustable iris (Lap Disc; Endo-Surgery, Cincinnati, OH, USA). With all of the above hand-assisted devices, the incision for the hand-assisted device can be made first, followed by secondary trocar placement [6].

Laparoendoscopic single-site surgery access

Single port laparoscopic surgery [laparoendoscopic single-site surgery (LESS)] has been introduced into several surgical fields: urology, general surgery, and gynecology. This novel technique consolidates all trocar sites to a single site, usually near the umbilicus. The combination working and laparoscopic lens ports can be inserted by the open (Hasson) approach (Uni-X Single Port Access Laparoscopic System; PNaval Systems, Cleveland, OH, USA) or a closed technique via an introducer after insufflation. The GelPort utilized for hand-assisted laparoscopic surgery can be used in a similar fashion for LESS surgery [7] (Figure 74.6).

Complications of accessing the peritoneal cavity

Complications of transperitoneal access are rare but must be promptly diagnosed and treated. The three main complications areas are vascular injury, bowel injury, and preperitoneal insufflation.

Access injuries related to the abdominal wall vessels and great vessels are a rare occurrence, reported at 0.25% [5]. These significant injuries can be nearly eliminated by the use of direct visual access or open access methods for introduction of the initial port. Diagnosis of access injury is confirmed by the return of large amounts of blood with placement of the Veress needle or initial port. Delayed recognition via laparoscopic lens will demonstrate brisk intraperitoneal bleeding. Laparoscopic management of large vessel bleeding associated with access is generally precluded since secondary working trocars have yet to be placed, thus necessitating rapid open conversion to control bleeding. On the other hand, abdominal wall vessel bleeding that is not brisk will afford secondary trocar placement for control of bleeding. If direct coagulation does not control the abdominal wall vessel, a Carter–Thomason closure device can be used to pass a figure-of-eight absorbable suture to control the bleeding before proceeding with the primary surgery.

Bowel injury during laparoscopic procedures occurs at an incidence of 0.13%. Approximately, one-third of these bowel injuries occur in obtaining initial access [8]. Prevention of access-related bowel injuries includes selecting an entry point furthest away from an abdominal wall scar and/or insufflation at or above the mid-clavicular line when in the flank position. Diagnosis of bowel injury during obtaining access can be suspected with aspiration of succus enterius or with uneven abdominal insufflation. If insufflation of colon or intestine is suspected, it is recommended to leave the Veress needle in place and to obtain peritoneal cavity access via

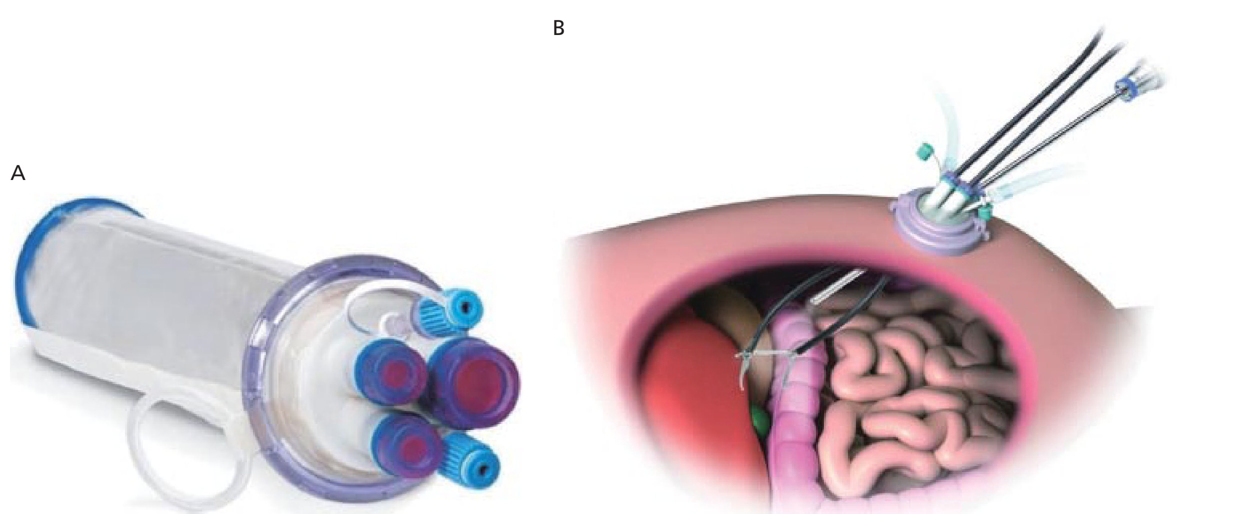

Figure 74.6 (A) Single-site surgery access device made by Olympus (Germany) has access channels for the laparoscopic lens and instruments. (B) Single-site surgery access device in place at the umbilicus, with laparoscope and working instruments in place.

an open technique away from the prior placed Veress needle. If the Veress needle is confirmed to enter into the bowel as an isolated injury, the area of injury can often be repaired via intracorporal laparoscopic suturing techniques. Larger injuries like thermal bowel injuries must be repaired via either laparoscopic or open techniques. If the suspected bowel injury is not found, the bowel has to be completely run.

Seventy percent of bowel injuries are not detected at the time of surgery. Subsequent presenting symptoms can be atypical and include focal trocar tenderness (often without rebound tenderness), leukopenia or diarrhea [8]. Since the delayed presentation of bowel injuries is atypical, a high index of suspicion must be exercised. Diagnosis can be confirmed with serial computed tomography (CT) scan showing increasing intraperitoneal gas [9]. Without early diagnosis and treatment, unrecognized bowel injury after laparoscopic surgery will progress to sepsis, Fornier's gangrene, and eventual death [8].

Preperitoneal insufflation is recognized by high opening pressures (>8–10 mmHg) with initial Veress needle placement coupled with a lower overall volume of insufflation volume compared to intraperitoneal insufflation. Unfortunately, this situation is not confirmed until the laparoscope is introduced into the preperitoneal space, revealing web-like attachments and the confining peritoneum without bowel. With a visual trocar, the peritoneum can be visualized as a collapsed space with intraperitoneal structures within the abdominal cavity. With gentle pressure, the lens can be advanced through the peritoneum.

Secondary trocar technique

After successful creation of the pneumoperitoneum and placement of the initial trocar, secondary trocars are placed under videoendoscopic vision. Prior to trocar placement, the intra-abdominal pressure is increased to 20 mmHg or greater. This increases the rigidity of the anterior wall, providing a stronger platform, which facilitates the downward trocar placement. The room is darkened and the laparoscope is used to transilluminate the anterior abdominal wall. This helps visualize the superficial anterior abdominal wall vessels, which aids in avoiding these structures (Figures 74.1 and 74.2). After the appropriate trocar site is selected, pre-emptive analgesics are injected into the area and a skin incision just large enough to admit the trocar is made along Langer's lines. The subcutaneous tissue is spread with a clamp to push the superficial vessels away from the trocar entry site. The secondary trocar site is checked by pushing downward at the site on the abdominal wall. While watching the interior structures via the camera, the appropriate entry site is recognized by the deformity of the peritoneal surface and is deemed safe or another site is chosen. Again, epigastric or abdominal wall vessels should be avoided.

For the traditional cutting trocar, the technique for placement is as follows. The trocar is held in the palm of the dominant hand with the middle finger extended to act as a brake [10]. If a shielded trocar (a trocar with a safety shield) is used, the shield should be in the set position. The side port stopcock is closed prior to placement. The cannula is placed in the direction of the dissection. However, if two separate operative fields are required, as in a nephrourerterectomy, the trocars are placed perpendicular to the abdominal wall.

All secondary cannulas are placed under laparoscopic monitoring. The incision site is checked to confirm that it is wide enough to accommodate the trocar. An insufficient skin opening can result in excess force being required to enter the peritoneal cavity. Forward pressure is applied using a slow continuous right-to-left twisting motion. The trocar tip is visualized as it enters the abdominal cavity by the deformity of the peritoneum. As the trocar tip comes close to the underlying viscera, it is redirected up and away from the viscera. Once the trocar tip is in the abdominal cavity, the safety shield springs forward. The trocar is advanced further into the abdominal cavity until the sheath is within the peritoneal cavity. The inner obturator is then removed and the sheath is advanced 1–2 cm within the peritoneal cavity.

Once the trocar is placed, it should be fixed in place to prevent accidental removal during dissection. Several manufacturers have integrated retentive grooves into the sheath or made detachable retentive grooves to prevent movement of the trocar sheath. In contrast to integrated grooves, the internal mesh of dilating trocars will function to prevent inadvertent trocar removal. Trocars can also be secured by placing a suture through the skin and tying the suture to the sidearm port. This suture prevents the trocar from being pulled out of the abdominal cavity, while allowing the operator to advance the trocar further into the peritoneal cavity. Radial dilating secondary trocars, VersaStep (Covidien), are placed under direct vision. A skin incision is made to admit the desired trocar size. The expandible mesh sleeve is back-loaded onto a 14G Veress needle. With no dissection of the subcutaneous tissue, this apparatus is passed through the abdominal wall under direct vision.

The inner Veress needle is removed, and a blunt-tipped fascial dilator is back-loaded with its corresponding cannula through a sleeve. It is critical to hold counter-traction with the nondominant hand while passing the dilator/cannula with the dominant hand (Figure 74.4). This step is facilitated by using a constant right-to-left twisting downward pressure. Care is taken to prevent inadvertant injury to intra-abdominal organs. Once the canula has been passed through the abdominal

wall, the obturator is removed and the canula depth is adjusted. No stay suture is needed to secure the radial dilating trocars. The fascial defect is reported to be one-half of that of the traditional cutting trocar and thus, there are fewer entry complications, gas leakage, trocar site bleeding, and hernia formation [10–13]. In addition, these studies have demonstrated less postoperative pain at the trocar site with the radial dilating trocars versus the tradition cutting trocars [10–13].

Primary trocar site inspection

After the initial secondary trocar has been placed, a laparoscope is passed through this cannula. The primary trocar site is inspected at its entry point into the peritoneal cavity [3]. If any abdominal viscera (omentum, bowel, etc.) have been traversed, appropriate reparative actions must be initiated. This is also the optimal time to secure the primary trocar to the abdominal wall. Additional secondary trocars are placed as outlined above.

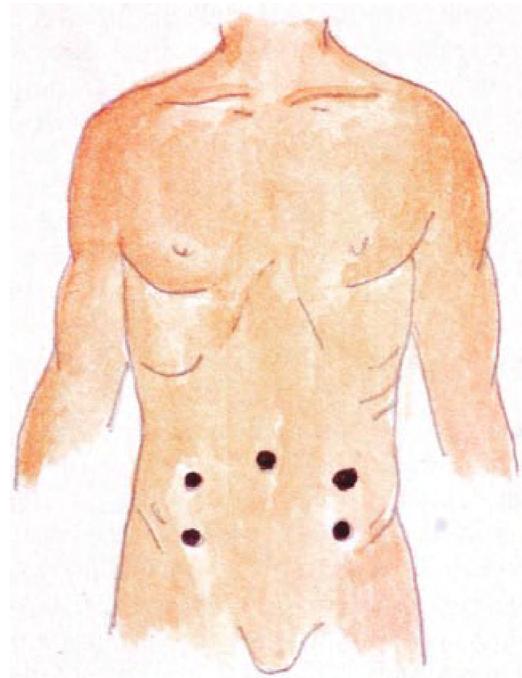

Figure 74.7 Fan configuration commonly used for performing pelvic lymph node dissection.

Secondary trocar configuration

Selection of trocar size and secondary trocar arrangement depend on the type of procedure and the surgeon's individual preference. Individual surgeons may choose different trocar configurations based on the patient's body habitus, surgical approach (transperitoneal vs extraperitoneal), and availability of specialized instruments. This section will give some basic secondary trocar arrangements for specific urologic procedures.

Laparoscopic pelvic procedures

Laparoscopic urologic pelvic procedures are performed with two different types of trocar arrangements: a fan or diamond array [2, 14–18]. Procedures utilizing the fan or diamond configurations include pelvic lymphadenectomy, bladder neck suspension, and radical prostatectomy.

In both of these trocar configurations at least two 10/12-mm trocars are needed. One 10/12-mm port is used for the camera and the other port is used for passage of suture material or to remove tissue. The fan configuration is advantageous because this allows use of both hands (Figure 74.7) and has been advocated for use in obese patients. A modified fan configuration (Figure 74.8) was designed for laparoscopic radical prostatectomies. In this configuration the lower trocars are moved from a lateral to a medial or paramedial position. The upper trocars are moved slightly lateral to the mid-calvicular line. This rearrangement allows specialized suturing instruments to reach deep into the pelvis where

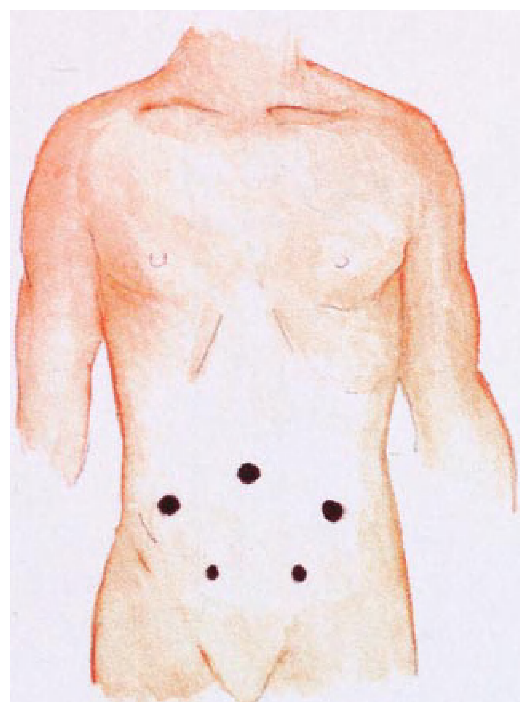

Figure 74.8 Modified fan configuration commonly used for laparoscopic radical prostatectomy and retropubic bladder neck suspension.

a vesicourethral anastomosis may need to be performed, or it may be useful in laparoscopic bladder neck suspension.

For pelvic procedures, the patient is often positioned in a dorsal lithotomy position. In this position the diamond trocar array (Figure 74.9) gives the surgeon maximal freedom in moving the suprapubic trocar, but they need to be aware that the medial umbilical ligament can interfere with instruments passed through the lower midline trocar of the diamond configuration. The diamond configuration is also used when a pelvic lymphadenectomy is being performed in conjunction with a laparoscopic-assisted perineal prostatectomy.

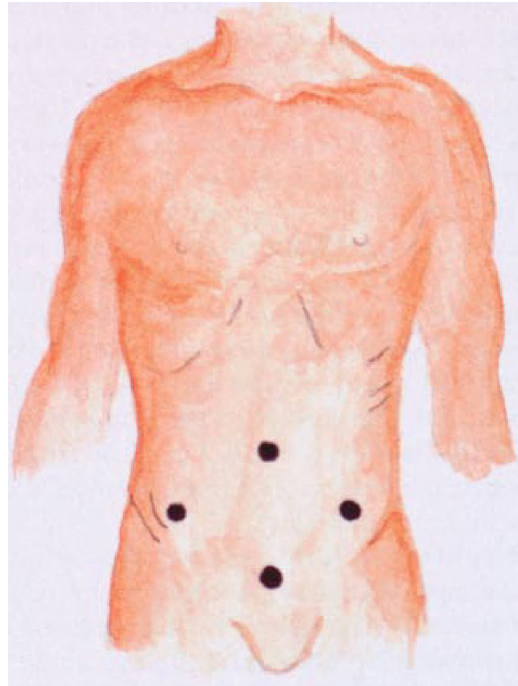

Figure 74.9 Diamond trocar configuration is utilized for either pelvic lymphadenectomy or bladder neck suspension.

Laparoscopic bladder neck suspension

When using a diamond trocar array (Figure 74.9) in performing a Burch bladder neck suspension, secondary trocar size depends on the reconstructive instrumentation utilized [17, 18]. For example, if an Endo Stitch® suturing device is used, all trocars placed will be 10/12 mm. If conventional suturing is used for securing the anterior vaginal wall to Cooper's ligament, then 5-mm trocars can be substituted. Alternatively, Frede *et al*. recommended a modified fan configuration (Figure 74.8) for laparoscopic bladder neck suspension [2].

Laparoscopic varix ligation/orchiopexy

When performing a varix ligation (unilateral or bilateral), three trocars are usually needed [19] (Figure 74.10). They are arranged in a triangular configuration. In addition to the primary umbilical 10/12-mm trocar or a 5-mm trocar for the camera, two secondary trocars are placed in the mid-clavicular line at the level of the anterior superior iliac spine. One of these mid-clavicular trocars is used for clipping the spermatic veins. This trocar arrangement also can be used when clipping the spermatic vessels in a staged orchiopexy.

Several 5-mm secondary trocars are needed to perform a laparoscopic primary orchiopexy for the treatment of intra-abdominal testes [20] (Figure 74.10). A 5-mm umbilical primary trocar is needed for the camera. Two 5-mm trocars are placed in the mid-clavicular line at the level of the anterior superior spine for dissection of the spermatic vessels. A final 5-mm trocar is placed through the scrotum into the peritoneal cavity for transfer of the intra-abdominal testes into the scrotum. This is accomplished by backfeeding a 5-mm trocar over a 5-mm straight grasper that has been passed through the mid-clavicular trocar (ispilateral to the intra-abdominal testes) over the pubic ramus and through the scrotal incision. This grasper is utilized to gently bring the intra-abdominal testicle into the scrotum.

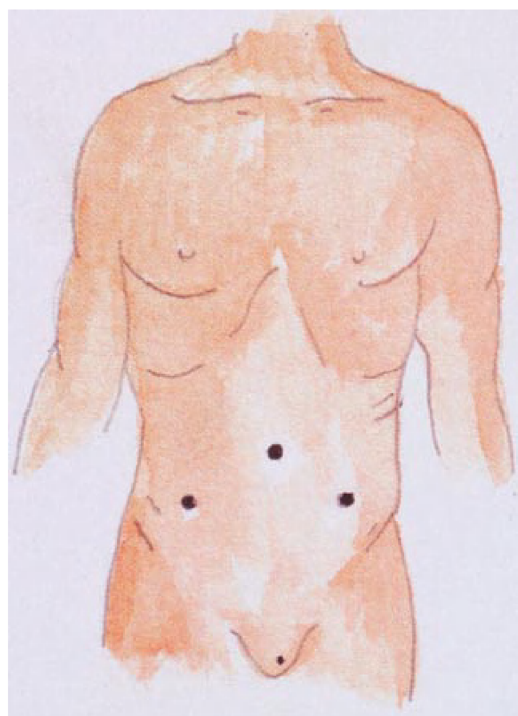

Figure 74.10 Triangular trocar configuration used for varix ligation (unilateral or bilateral) and primary orchiopexy. A 5-mm scrotal trocar is used to deliver the testicle into the scrotum.

Figure 74.11 Three trocars are utilized to perform a reconstructive upper ureteral procedure. An optional 5-mm trocar can later be placed in the anterior axillary line for refraction of a large redundant renal pelvis and as the exit point for a retroperitoneal drain.

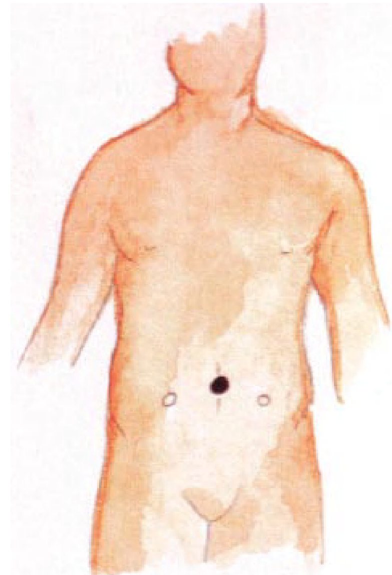

Figure 74.12 Trocar arrangement for access to the pelvic ureter. A triangular arrangement is advocated with a 10/12-mm port at the umbilicus and two 5-mm ports as shown.

Pure laparoscopic ureter procedures

Port placement to access the abdominal ureter includes a port placed just lateral to the umbilicus. Another port is placed below the costal margin in the mid-clavicular line and the third trocar is positioned in the lower ipsilateral quadrant in the mid-clavicular line (Figure 74.11). Trocar placement for the lower pelvic ureter includes a trocar at the umbilicus. One to two ports are placed in each lower quadrant 2 cm medial to the corresponding anterior iliac spine. This configuration provides optimal access to the pelvic ureter from the iliac vessels to the ureterovesical junction (Figure 74.12). When access to the entire ureter is a concern, a combination port placement is necessary (Figure 74.13). Three to four trocars are required to perform a transperitoneal laparoscopic procedure on the upper ureter [21]. A periumbilical 12-mm primary trocar is used for the videoendoscope. A 10/12-mm trocar is placed in the mid-clavicular line at the level of the umbilicus. Two 5-mm trocars are used, one in the epigastric area and one in the anterior axillary line between the iliac crest and 12th rib. Suture passage is via the mid-clavicular trocar, while suturing is performed via both the mid-clavicular and epigastric trocars (port placement for pyeloplasty or ureterolysis

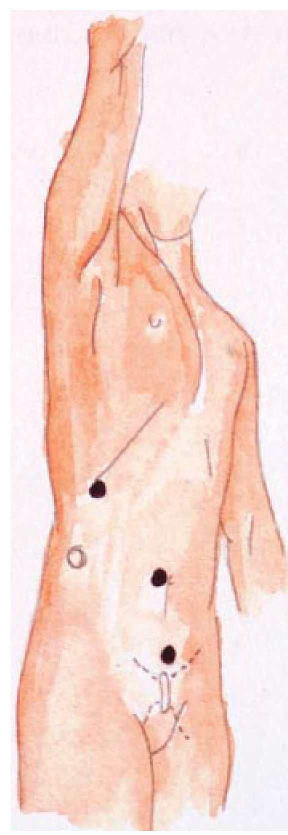

Figure 74.13 Combination port placement for access to the entire ureter (modified from Figure 60.6 in *Smith's Textbook of Endourology*, 1st edn).

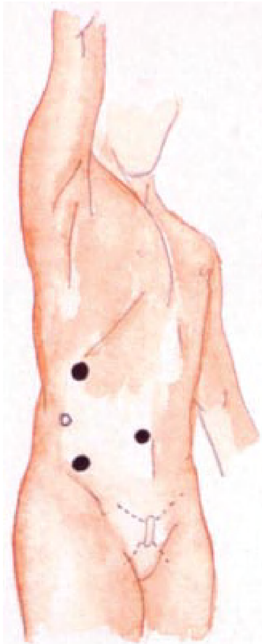

Figure 74.14 Port placement for laparoscopic pyeloplasty is similar to the abdominal ureter port placement. However, an additional 5-mm trocar may be placed in the anterior axillary line midway between the costal margin and iliac crest for retraction. Port placement for laparoscopic ureterolysis is similar to that for laparoscopic pyeloplasty. In this case the 5-mm port is used for retraction.

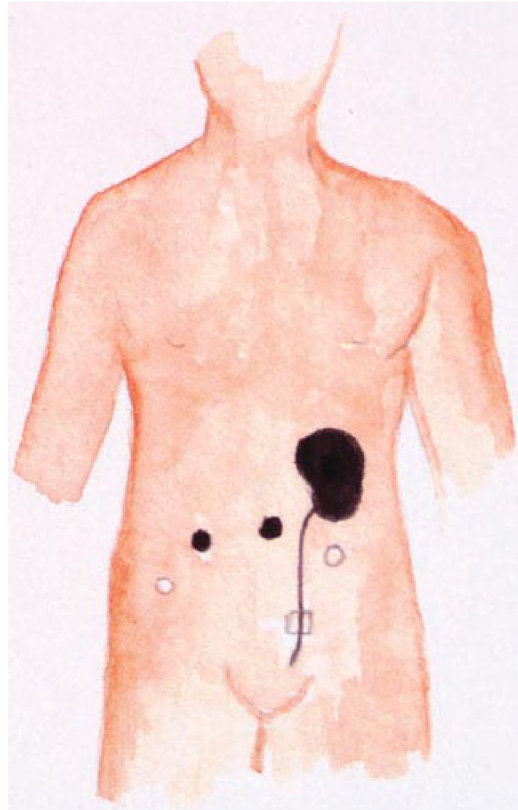

Figure 74.15 Trocar configuration for a left lower laparoscopic ureterolithotomy. The 10/12-mm port is placed contralateral to the side in question.

is shown in Figure 74.14). Ureterolithotomy port placement is dependent on whether the upper or lower ureter is involved. A stone located in the upper ureter can be approached similar to a pyeloplasty procedure, while for lower ureteral stones the 10-mm port is placed contralateral to the side to be addressed (Figure 74.15).

Pure laparoscopic renal procedures

Nephrectomy

Three to five trocars are needed to carry out a transperitoneal laparoscopic nephrectomy and other laparoscopic renal surgeries [22] (Figure 74.16). A 10/12-mm periumbilical cannula is used for the camera. The dissection ports are placed at the epigastric and mid-clavicular position, similar to the positioning used for performing a laparoscopic procedure on the upper ureter. If an endovascular stapler or vascular "bulldog clamp" is to be utilized for vascular control, one or both of these trocars needs to be a 10/12-mm trocar(s). Additional laterally placed trocars are used for retraction of the renal helium, lateral dissection, or suture repair, as well as treatment probe insertion for nephron-sparing procedures. In all cases the lateral trocars are either 5 or 8 mm in size, with the exception of cytoreductive nephrectomy when a endovascular stapler is needed to control the parasitic vessels; in this case 10/12-mm lateral trocars are used.

Nephroureterectomy

Trocar configuration for laparoscopic nephroureterectomy is identical to the configuration utilized for the laparoscopic nephrectomy. An additional suprapubic port is used to secure the bladder cuff (Figure 74.17). Some surgeons utilize a vascular GIA stapler to complete this task. When using the GIA stapler, a 10/12-mm suprapubic trocar is needed. Other surgeons perform primary resection with subsequent conventional suturing reconstruction of the bladder. This requires a 5-mm trocar.

Donor nephrectomy

Laparoscopic transperitoneal donor nephrectomy requires the same primary three trocars utilized for laparoscopic simple nephrectomy and additional retraction trocars. For left laparoscopic donor nephrectomy, a 15-mm suprapubic trocar is used for medial retraction

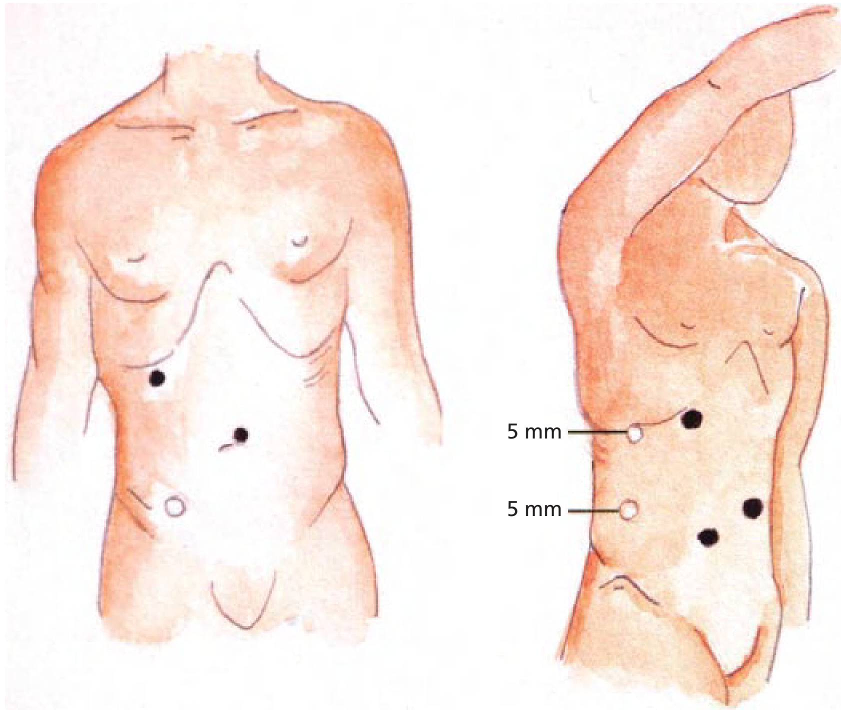

Figure 74.16 Trocar configuration for laparoscopic nephrectomy/partial nephrectomy varies from three (left) to five trocars (right). Two 12-mm ports are placed initially at the umbilicus and upper mid-clavicular line. Three other ports, which may be 5-mm ports, are placed at the lower mid-clavicular line, lower anterior axillary line, and upper anterior axillary line. At times the upper axillary line port may be changed for a 12-mm port.

of the bowel (Figure 74.18). For right-sided procedures this trocar is moved upward to the epigastic region. Trocar configuration for left-sided hand-assisted donor nephrectomy starts with an epigastric placed hand-assisted device. In addition, two 12-mm ports are placed at the umbilicus and mid-clavicular area with an optional (if retraction is needed) lateral 5-mm port placed at the anterior axillary line (Figure 74.19).

Partial nephrectomy/calyceal diverticulectomy

During laparoscopic partial nephrectomy or calyceal diverticulum resection, laterally placed trocars are used for renal resection, renal reconstruction, or drain placement (Figure 74.16). It is important to remember in the morbidly obese patient to move all trocars laterally and to place the midline trocars in the paramedian line [23].

Hand-assisted nephrectomy

The trocar configuration for hand-assisted laparoscopic nephrectomy (HALN) is very different from both transperitoneal and retroperitoneal laparoscopic nephrectomy. Secondary trocar arrangement is dependent on placement of the hand-assisted device and is arranged to optimize visualization with the camera port and dissection with the two working instruments. As with traditional laparoscopic procedures, these three ports are arranged in triangular configurations. For left-sided HALN, the hand-assisted device is placed within the periumbical area with the working port and camera ports placed in the mid-clavicular line and anterior axillary line, respectively (Figure 74.19A). For right-sided HALN, the hand-assisted device is placed in the right lower quadrant with the working and camera ports placed in the periumbilical area and epigastric area, respectively (Figure 74.19B).

Adrenalectomy

Laparoscopic adrenalectomy has multiple trocar placement configurations, depending on approach (transperitoneal vs retroperitoneal vs thoracic) and side of interest (right or left). For right-sided transperitoneal adrenalectomy, the trocars are arranged in a circular configuration. The camera port (10/12 mm) is placed in the periumbilical region. The dissection trocars are positioned in the anterior axillary and mid-axillary line. A fourth port is placed between the two above trocars and utilized for retraction of the liver (Figure 74.20). An optional fifth port can be placed in the posterior axillary to retract the upper pole of the kidney. Trocars are placed

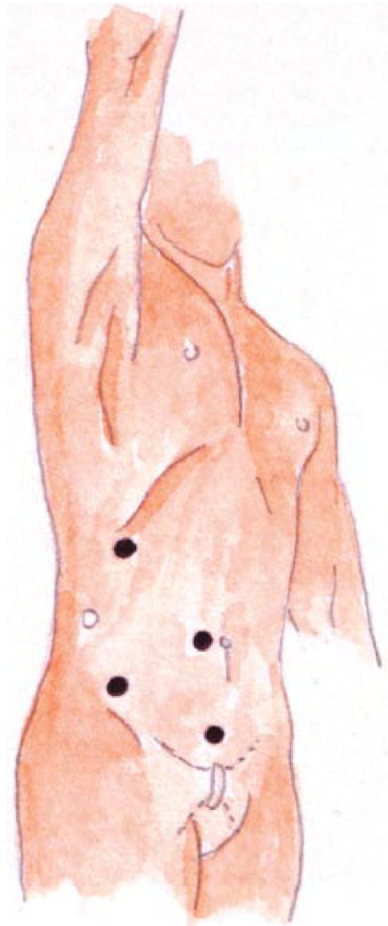

Figure 74.17 Trocar arrangement for laparoscopic nephrouretertomy. The 12-mm port is used for passing the GIA stapler across the bladder cuff. Again, placing a 5-mm port for retraction is optional.

in similar fashion for performing a left transperitoneal adrenectomy. Lastly, Gill *et al.* have reported thoracoscopic transdiaphragmatic adrenalectomy with the four-port configuration depicted in Figure 74.21.

Retroperitoneal lymph node dissection

Four to five ports are usually used. Some surgeons recommend only 10/12-mm ports to allow maximal flexibility and this enables use of larger grasping forceps for specimen retrieval. Port positioning for laparoscopic retroperitoneal lymph node dissection for testicular cancer is a diamond-shaped configuration with the camera port at the umbilicus. Two 12-mm working ports are placed in the mid-clavicular line, one at the costal margin and one at the level of the anterior superior spine. A lateral retraction port is placed in the anterior axillary line at the level of the umbilicus (Figure 74.22).

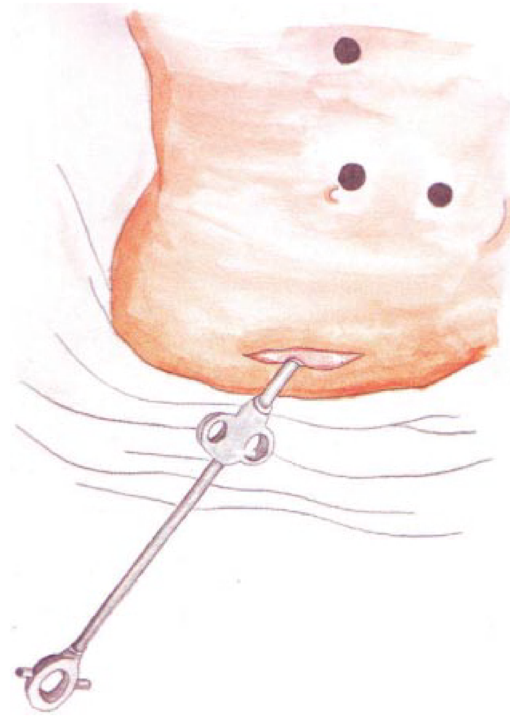

Figure 74.18 Trocar arrangement for a left laparoscopic donor nephrectomy. A suprapubic "thoracoport" and Endo Catch II entrapment device may be useful at the extraction site.

Robot-assisted laparoscopic procedures

The da Vinci robotic system has become widely used in the USA and Europe for urologic procedures which require reconstruction (prostatectomy, partial nephrectomy and pyeloplasty). This section will demonstrate the recommended trocar configuration for commonly used robot-assisted laparoscopic procedures (prostatectomy, nephrectomy, partial nephrectomy, and pyeloplasty).

Prostatectomy

Port placement for robot-assisted laparoscopic radical prostatectomy is based on the most consistent anatomic landmark, the pubic bone in the midline. Another consideration in any robot-assisted procedure is that the maximum working length of the da Vinci instruments is 25 cm. Therefore, for robot-assisted prostatectomy all robotic instrument ports are positioned approximately 15 cm (not to exceed 18 cm) from the patient's midline of the public bone. The 12-mm scope port is positioned superior umbilically within 2 cm of the umbilicus. All robotic working ports are 8 mm in diameter and are three- or four-arm, based on the da Vinci robotic model. The right robotic working port (labeled 1 and colored yellow) is positioned 10–12 cm (one hand's width) from the midline on a line to the right anterior iliac spine

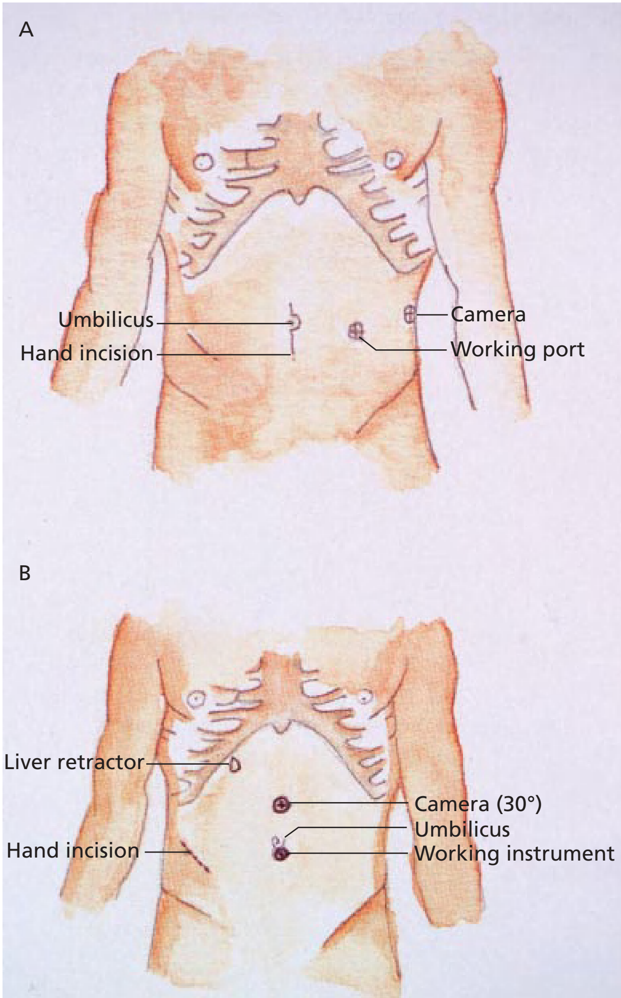

Figure 74.19 (A) Positioning of hand-assisted device and trocar configuration for (A) left-sided and (B) right-sided hand-assisted nephrectomy.

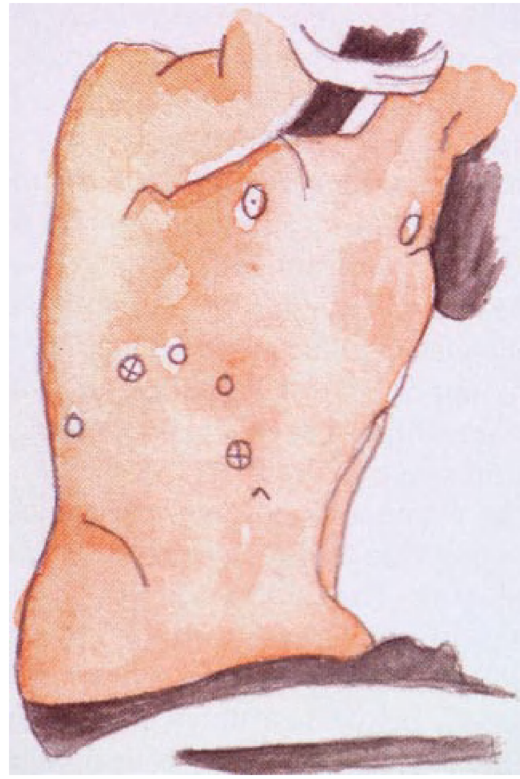

Figure 74.20 Four ports are typically used for a transperitoneal laparoscopic adrenalectomy. The first trocar is usually placed in the anterior axillary line. Next, two others are placed under vision at the subcostal mid-clavicular and midline. After the kidney has been identified, a fourth trocar may be placed subcostally in the posterior axillary line.

slightly below the level of the scope port. The left robotic working port (labeled 2 and colored green) is positioned 10–12 cm from the midline on a line to the left anterior superior iliac spine, slightly below the scope port. The third working arm port (labeled 3 and colored red) is positioned on the patient's right side 2–3 cm from the right superior iliac crest and within 8 cm (one hand's width) from the right robotic working port [1]. Assistant port 1 (white, 12 mm) is positioned on the patient's left side, one hand's width lateral to the left robotic working port (labeled 2 and colored green). Assistant port 2 (black, 5 mm) is positioned on the patient's left side 6–8 cm above the left robotic working port (Figure 74.23).

Nephrectomy

Robot-assisted nephrectomy and partial nephrectomy has two types of trocar configurations: medial camera

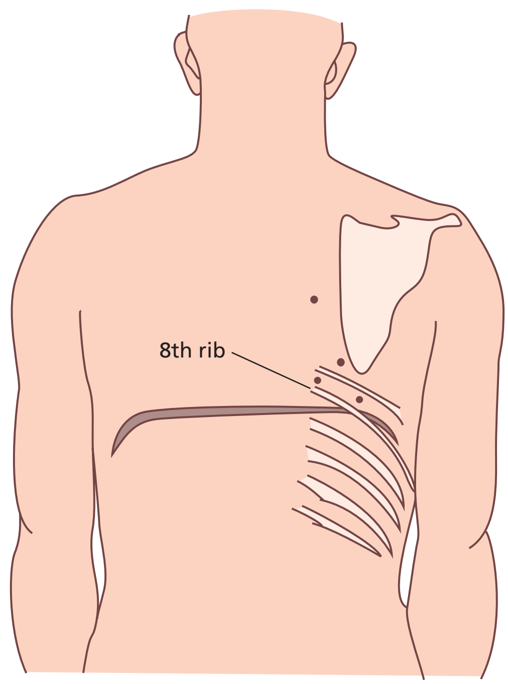

Figure 74.21 Trocar configuration using Gill's right transthoracoscopic approach to an adrenalectomy [24].

port placement and lateral camera port placement. General principles to keep in mind when placing trocars is to triangulate the ports toward the renal hilum, and to create obtuse angle of approximately 100° between the robotic ports and camera port as the vertex. The medial camera port placement technique uses a 0° or 30° angle-down scope with the patient in a full or modified flank patient position. The major advantage is a viewing perspective similar to that with traditional laparoscopic renal surgery. The lateral camera port placement technique uses a 30° angle-up laparoscope with the patient positioned in the full flank position. Major advantages of the lateral camera port are the aerial viewing perspective, reduced number of robotic arm and camera arm collisions, and the optimized working space for the patient-side assistant.

For medial camera port configuration for nephrectomy and partial nephrectomy procedures, the camera port (12 mm) is placed in the periumbilical area (Figure 74.24A). For left-sided procedures, the robotic instrument ports are placed a hand's width away from the camera port with each trocar (8 mm) at least 3 cm from the iliac crest (yellow) and costal margin (green). For right-sided procedures, the robotic working ports are placed a hand's width away from the camera, with each trocar (8 mm) at least 3 cm from the costal margin (yellow) and iliac crest (green). Also, the robotic working ports are placed a hand's width away from the camera, with each trocar (8 mm) at least 3 cm from the costal margin (yellow) and iliac crest (green) (Figure 74.24B).

For the lateral camera port configuration, the camera port (12 mm) is placed a hand's width from the costal margin, between the mid-clavicular and anterior axillary line. For right-sided procedures, both robotic instrument ports (8 mm) are placed a hand's width medial from the camera port (Figure 74.25A), with the right robotic working port placed at least 3 cm from the costal margin and the left robotic working port at least 3 cm from iliac crest. For left-sided procedures the robotic instrument working ports are both placed a hand's width medial to the camera port (Figure 74.25B), with the right robotic working port placed at least 3 cm from the iliac crest and the left robotic working port at least

Figure 74.22 Trocar positioning is in an "X" arrangement for a right retroperitoneal lymphadenectomy for testicular cancer. Usually the surgeon will use laparoscopic scissors at the infraumbilical port and grasping forceps at the lower quadrant port. The contralateral port is optional and may be used by an assistant. The upper right quadrant port is the camera site.

3 cm from the costal margin. The superior assistant port (12 mm)- is placed periumbilical and the inferior assistant port (5 mm) 8 cm inferior to the umbilicus and at least 4 cm from the inferior robotic instrument port.

Pyeloplasty

For robot-assisted laparoscopic pyeloplasty, the camera port is placed at the umbilicus. For obese patients this port can be moved lateral to the rectus muscle. The robotic working ports are placed 8–10 cm lateral to the camera port. For right-sided procedures, the right robotic instrument port is 3 cm from the costal margin and the left robotic instrument port is 3 cm from the iliac crest (Figure. 74.26A). For left-sided procedures, the right robotic instrument port is 3 cm from the iliac crest and the left robotic instrument port is 3 cm from the costal margin (Figure 74.26B).

Conclusions

With careful planning, secondary trocars can be placed safely and effectively under videoendoscopic vision. For surgeons who are at an early stage on the learning curve, we recommend using an established trocar placement for a given procedure and suggest modifying this as experience is gained to fit personal preferences and experience with established trocar arrangements. As the experienced laparoscopic surgeon well knows, the prudent arrangement of the laparoscopic trocars can mean the difference between effortlessly orchestrated procedures and a tiresome mêlée.

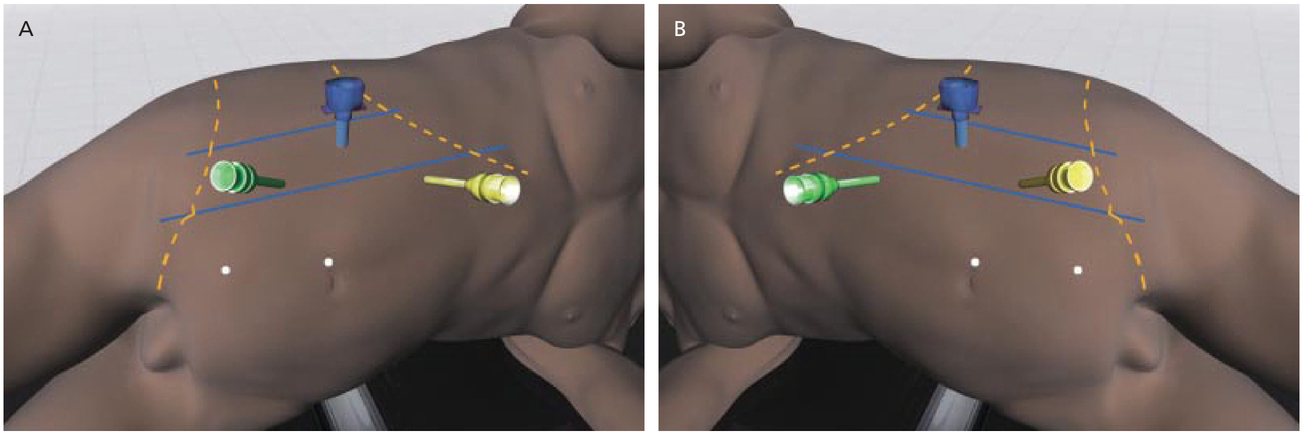

Figure 74.26 (A) Robot-assisted pyeloplasty for (A) right-sided and (B) left-sided port configuration. Camera port, blue; left robotic working port, green; right robotic working port, yellow; assistant ports, white (© 2010 Intuitive Surgical Inc, Sunnyvale, CA, USA).

CHAPTER 75
Retroperitoneal Access

Ali Moinzadeh
Institute of Urology/Urologic Oncology, Lahey Clinic Medical Center, Burlington, MA, USA

Introduction

The first technical part of any urologic laparoscopic or robotic procedure involves obtaining access to either the peritoneum (see Chapter 74) or the retroperitoneal space. Access and trocar placement is of critical importance as improper placement may lead to difficulty later. In this chapter we outline the necessary steps for proper patient position, access, and secondary trocar placement for both renal retroperitoneal surgery and pelvic extraperitoneal surgery. In addition, we outline potential exclusion criteria for retroperitoneal renal/adrenal surgery and extraperitoneal pelvic surgery. Finally, we briefly summarize critical issues related to laparoscopic exit at the end of the case.

Retroperitoneal renal/adrenal surgical access

Direct access to the retroperitoneum for renal or adrenal surgery may offer several potential advantages over the transperitoneal approach. Ligation of the renal artery and vein during radical nephrectomy may be aided by circumventing the need for bowel dissection. In addition, in cases of posterior small renal masses, direct access to the posterior aspect of the kidney may obviate the need for full renal mobilization. Patients with multiple prior transabdominal surgeries or large anteriorly located mesh may also benefit from the retroperitoneal approach for renal or adrenal surgery.

Patient exclusion

A surgeon's experience often dictates their preference between transperitoneal and retroperitoneal access. No definitive exclusion criteria exist for retroperitoneal access, although a few cases may present more challenges for retroperitoneal surgery. As such, the novice surgeon should be selective when choosing patients. Renal tumors greater than 10 cm in size are best approached via a transperitoneal approach. Those located on the posterior hilar aspect may present challenges with retraction and lifting of the kidney and as such may be better suited for the transperitoneal approach. A patient with prior open retroperitoneal surgery (e.g. a partial nephrectomy) is best approached transperitoneally or in an open fashion. Prior percutaneous access for stone surgery has not presented a significant challenge in our experience.

Patient position and access technique

After induction of general anesthesia, the patient is positioned in the full flank position. The patient is secured to the table with 3-inch tape at the level of the chest (without impeding mechanical ventilation) and hips. Securing the patient in this way allows the table to be rotated from right to left. We do not find it necessary to use a bean bag. The table is flexed and an axillary roll is placed. Pillows are placed between the legs and pressure points (knees, hips) are properly padded. The

Smith's Textbook of Endourology, Third Edition. Edited by Arthur D. Smith, Gopal H. Badlani, Glenn M. Preminger, Louis R. Kavoussi.

upper extremity is placed in a double arm board. The tip of the 12th rib is marked with semi-permanent ink prior to sterile prep and drape, as palpation of the rib after preparation and gloving may be impaired, especially in the obese patient. After sterile preparation and draping, a line is extended from the anterior superior iliac spine in a cephalad direction, and the right surgical port is inserted along this line (Figure 75.1). Another line is drawn at the level of the extensor muscles of the back. At the intersection of this line and the lower aspect of the 12th rib, the left trocar is inserted.

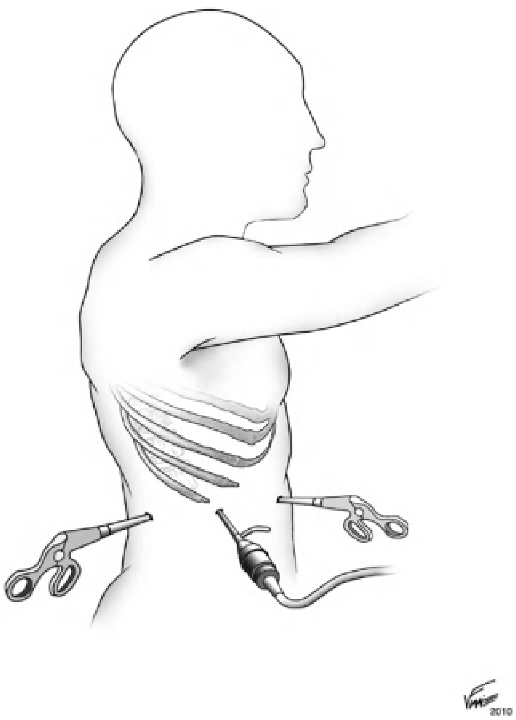

Figure 75.1 Trocar placement for retroperitoneal renal/adrenal surgery. Patient is positioned in the full flank position. All three trocars line up in a straight line.

At the tip of the 12th rib, a 1.5-cm incision is made. The incision is carried down to the level of the external oblique fascia. A 1-cm incision is made in the fascia with Bovie cautery. S-retractors are used to split the external oblique muscle and often the internal oblique muscles down to the lumbodorsal fascia. The lumbodorsal fascia is incised with cautery of about 1 cm in length. The surgeon's index finger is inserted into the retroperitoneal space with the tip of the finger aimed in the posterior direction, but staying anterior to the psoas muscle which is readily palpable (Figure 75.2A). The lower pole kidney can typically be felt. Enough space is created posterior to the kidney so as to accommodate placement of the round dissecting balloon (Covidien, Mansfield, MA, USA), which is placed posterior to the kidney. The balloon is pumped 20 times (~400 mL). At this point a 30° lens, 10-mm laparoscope is inserted through the dissecting balloon port and the anatomy is appreciated. The psoas muscle can typically be assessed posteriorly and the peritoneum anteriorly. An additional 400 mL is insufflated into the balloon (800 mL in total) (Figure 75.2B). The balloon dissecting trocar is deflated and a balloon working trocar (Covidien) is placed. Retropneumoperitoneum is achieved at a pressure of 15 mmHg.

Placement of secondary trocars

Under direct vision the two remaining trocars are placed. The surgical left hand is placed under the 12th rib in line

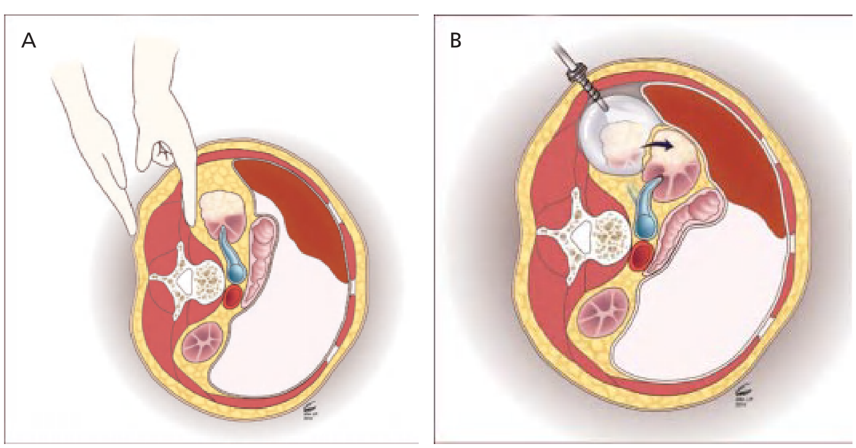

Figure 75.2 (A) Surgeon's index finger inserted through the lumbodorsal fascia into the retroperitoneal space anterior to the psoas muscle. (B) Balloon dissection of the retroperitoneum. The round-shaped balloon is posterior to the kidney during dissection.

with the extensor muscles of the back. This trocar may be angled in a slightly more cephalad direction, which will decrease the amount of torque on the trocar and surgeon fatigue during the case. The surgical right trocar is placed in line with the previously marked anterosuperior iliac spine (ASIS) line. The peritoneum may be visualized and, if necessary, may be dissected more medially using the surgical left trocar and a laparoscopic Kitner instrument. We use two 12-mm trocars for the left and right operating trocars. The surgical left trocar, camera trocar, and right trocar are all placed in a straight line (Figure 75.1).

Access for extraperitoneal pelvic surgery

The application of pelvic extraperitoneal surgery is best for robot-assisted laparoscopic prostatectomy. Other urologic applications include distal ureter surgery, partial cystectomy of anterior lesion, and limited pelvic lymph node dissection. An advantage of the technique is decreased need for a steep Trendelenburg position during the procedure. Patients with multiple prior abdominal surgeries (but virginal extraperitoneal space) with known or suspected bowel adhesions may be ideal candidates. In the event of vesicourinary anastomotic leak, the leak is contained in the extraperitoneal space. Disadvantages include the smaller working space and the higher rate of pelvic lymphocele if bilateral lymph node dissection is performed.

Patient exclusion

The transperitoneal approach is best for patients with prior extraperitoneal surgery, such as open simple prostatectomy, open bladder stone removal, and renal transplantation. In such cases, it may not be possible to dissect the space of Retzius with the balloon for safe placement of lateral trocars.

Patient position and access technique

The patient is placed in the supine position. Lower extremities may be placed in Yellofin® leg holders or using a split-leg table. An orogastric tube is placed by anesthesiology, and the patient is prepared and draped sterilely. The pubic bone is identified and an infraumbilical incision of about 1.5 cm in length is made in the midline. S-retractors are used for retraction and dissection is continued to the external fascia. Stay sutures of 0-vicryl are placed in the external fascia, caudal and cephalad to the incision site on the fascia. Holding the lower fascia anteriorly, the external fascia is incised. The rectus muscle belly is separated in the midline. A very thin layer of investing fascia of the muscle (no proper posterior sheath exists at this level) is identified and incised with scissors or blunt index finger dissection. The surgeon's index finger is inserted into the extraperitoneal space. A kidney-shaped dissecting balloon (Covidien) is inserted into the space in the direction of the pubic bone (Figure 75.3). The balloon is insufflated 30 times (~600 mL). Under direct vision with a 10-mm laparoscope, insufflation is continued until the pubic bone is visualized from within the balloon. The dissecting balloon is desufflated and removed. Care is taken to avoid distraction of the inferior epigastric vessels during insufflation. A Hasson trocar of the surgeon's choice is then placed to serve as a camera trocar (12 mm for robotic cases; 10 mm for laparoscopic cases).

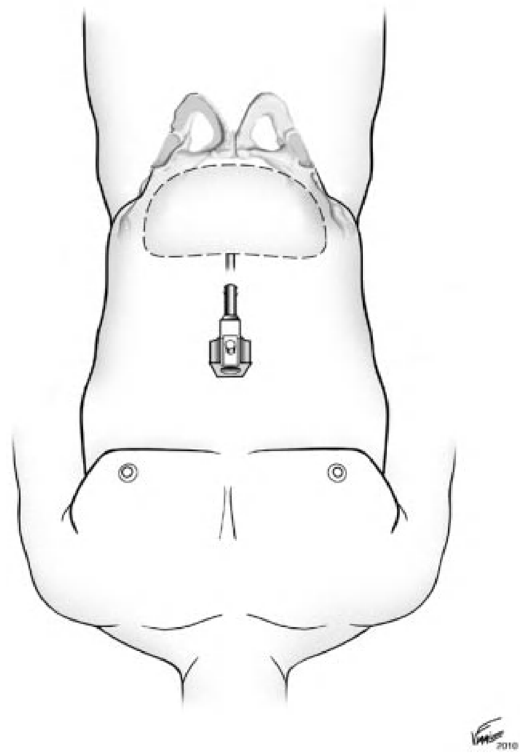

Figure 75.3 Extraperitoneal balloon dissection for laparoscopic or robotic pelvic surgery.

Placement of secondary trocars

It is necessary to push the peritoneum in a cephalad and lateral direction to allow placement of lateral secondary trocars. Despite the use of the kidney-shaped dissecting balloon, we find it necessary to use a 10-mm laparoscope and some gentle abdominal pressure to sweep the peritoneum in a cephalad and lateral direction. Pulsations of the iliac vessels should be noted to avoid inadvertent injury.

Laparoscopic exit

Although great emphasis is placed on initial access, of equal importance is the exit or removal of trocars at the end of the case. It may be challenging for the surgeon to follow through with these steps due to fatigue, but it is necessary for them to maintain vigilance at the end of the case. Details of the laparoscopic exit are given in Chapter 29. Here we describe the important features of exit from retroperitoneal and extraperitoneal surgery. If an inadvertent entry was made into the peritoneum during retroperitoneal surgery, the surgeon should explore this area and insure no bowel injury has occurred. The surgeon may decrease insufflation pressures to 10 mmHg or less to insure no bleeding is visualized. It is standard practice to remove all trocars under direct vision. In the event of bleeding from trocar sites, a Carter–Thomas closing device may be used to close the fascia and obtain hemostasis. Large 12-mm trocar sites may be closed with the Carter–Thomas closing device and Vicryl suture. For extraperitoneal pelvic surgery it is prudent to create a small peritoneal window at the level of the umbilicus at the end of the case to expel pneumoperitoneum that will have accumulated.

CHAPTER 76

Basic Hand-Assisted Laparoscopic Techniques

J. Stuart Wolf Jr
Department of Urology, University of Michigan, Ann Arbor, MI, USA

Introduction

The introduction of hand-assisted laparoscopic surgery (HALS) has contributed greatly to the widespread adoption of laparoscopy for renal surgery. With each passing year, more urologists are performing laparoscopy, specifically laparoscopic nephrectomy. The increase in use, however, was very modest in the first decade following Clayman *et al.*'s initial report [1]. Why did laparoscopic nephrectomy take so long to catch on, but then subsequently become a standard procedure? This history of laparoscopic nephrectomy contrasts starkly with that of other laparoscopic procedures introduced in the same time period (late 1980s to mid 1990s). Laparoscopic cholecystectomy, laparoscopic pelvic lymph node dissection [until its utility was reduced by prostate-specific antigen (PSA) risk profiling], laparoscopic gastric fundoplication, and laparoscopic hysterectomy all achieved widespread use soon after their introduction. Why was laparoscopic nephrectomy different? The primary reason proposed in the mid 1990s was that laparoscopic nephrectomy was too difficult for the average urologist to develop and to maintain the necessary operative skills, given the relative infrequency of nephrectomy in a typical urology practice. There were other factors as well, including concern about oncologic efficacy, the inefficiency of increased operative time, and safety of the procedure in case of vascular injury.

Although there likely were many developments that spurred on the widespread acceptance of laparoscopic nephrectomy, HALS was a major factor. HALS addresses many of the perceived problems with laparoscopic nephrectomy: it technically simplifies the procedure, which allows even urologists with a low-volume practice to develop and maintain skills; it facilitates wide dissection and intact specimen removal, which may provide some reassurance as to the oncologic efficacy of the procedure (although there is no evidence that HALS provides any different outcome from standard laparoscopic nephrectomy in this regard); it reduces operative time for most surgeons; and it provides more rapid control of vascular injury and may reduce the need for conversion to open surgery. Once a critical mass of surgeons started performing laparoscopic nephrectomy, combined with patient demand, its popularity was inevitable.

Following a brief history of hand assistance, this chapter first describes the HALS devices that are currently available along with some general principles of their application. Then, the results of HALS are provided with emphasis on series that compare HALS to other laparoscopic techniques. Finally, an assessment of the role of HALS in urology is made.

History

As with many innovations in surgery, the initial forays into HALS were met with skepticism [2]. In 1993, Boland *et al*. reported their experience (starting in 1992) with insertion of a gloved hand through a tight fascial incision to allow direct manual organ dissection and removal while maintaining pneumoperitoneum during laparos-

Smith's Textbook of Endourology, Third Edition. Edited by Arthur D. Smith, Gopal H. Badlani, Glenn M. Preminger, Louis R. Kavoussi.

copy [3]. Tierney *et al.* [4] and Tschada *et al*. [5] reported laparoscopic radical nephrectomy using this technique in 1994 and 1995, respectively. Commercial devices to facilitate laparoscopic hand assistance were under development by this time [6], and in 1996 Bannenberg *et al.* reported hand-assisted laparoscopic nephrectomy in a porcine model using a prototype of the first commercial HALS device [7]. Later that same year, Nakada *et al*. performed the first clinical laparoscopic nephrectomy with a commercial HALS device [8]. In 1997, Keeley *et al.* reported the first HALS nephroureterectomy [9], and in 1998 Wolf *et al.* described the first HALS donor nephrectomy [10]. HALS was soon applied to a number of other urologic laparoscopic procedures. The introduction of improved commercial HALS devices that did not require the use of a sleeve further accelerated the acceptance of HALS in urology.

Figure 76.1 Gelport® (courtesy of Applied Medical, Rancho Santa Margarita, CA; USA).

Devices for hand-assisted laparoscopy

The first commercial HALS devices had sleeves that wrapped around the arm and were affixed to the abdomen with adhesive: the Pneumo Sleeve (Dexterity Surgical, Roswell, GA, USA) and the Intromit (Medtech Ltd, Dublin, Ireland). The HandPort (Smith & Nephew, Andover, MA, USA) also had a sleeve, but the base was held on the abdomen with inflatable compression rather than adhesion. None of these devices remains in production. Lessons learned through their use, however, prompted the development of the improved devices that did not require a separate sleeve.

There are two commercial devices for HALS currently available. The Gelport® (Applied Medical, Rancho Santa Margarita, CA; USA; Figure 76.1) has two components that fit together on the abdomen, affixed by compression and providing gas occlusion with a gel that fits snugly around the surgeon's forearm. The Dextrus™ Access Port (Ethicon Endo-surgery, Cincinnati, OH, USA; Figure 76.2) replaced the Lap Disc®, which was of similar design. It also has two components and is also held within the abdominal incision by compression, but the gas occlusion is achieved with an iris valve that closes around the surgeon's forearm. A final second-generation device, the Omniport (Advanced Surgical Concepts, Wicklow, Ireland), was a cylinder that inflated to provide both abdominal fixation and gas occlusion; it is no longer manufactured.

Figure 76.2 Dextrus™ Access Port (courtesy of Ethicon Endo-Surgery, Cincinnati, OH, USA).

Gelport®

The Gelport® kit contains the Alexis® wound retractor, which is a pair of plastic rings connected by a flexible skirt that holds the abdominal incision open and provides the base for the second component, and the Gelseal® cap, which snaps onto the outer ring of the wound retractor to provide a gas-tight seal through which a hand or laparoscopic ports can be placed. The abdominal incision is made initially, and then the flexible ring of the wound retractor is inserted into the abdomen, leaving the rigid ring outside (Figure 76.3). The outer ring is rotated inward to shorten the skirt and pull the rings tight against the abdominal wall (Figure 76.4). Once the gel cap is snapped onto the outer ring, the abdomen is gas tight (Figure 76.5). The gel expands enough to allow insertion of a hand through its central slit (Figure 76.6), but also will occlude the incision with nothing passing through it. In addition, ports can be

passed through the central slit in the gel, or through a separate stab incision in the gel (Figure 76.7). An instrument can be passed through the gel alone, or when the hand is in place.

Dextrus® Access Port

The Dextrus® Access Port also is a two-piece device. The base is a fixed length wound retractor comprised of an inner flexible ring and an outer rigid ring connected by an elastic skirt that holds the abdominal incision open and provides the base for the second component. The outer cap is a pair of locking rings that snap onto the base and close an iris valve to provide gas occlusion. The fixed length wound retractor, which is available in three sizes to accommodate abdominal walls of varying thickness, is inserted into the abdomi-

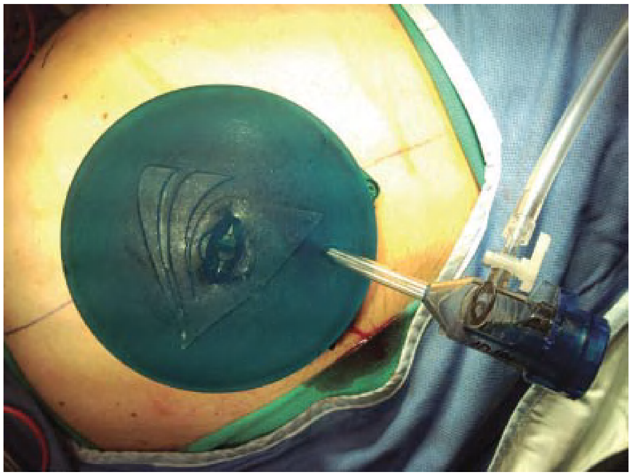

Figure 76.7 Gelseal® kit: a laparoscopic port can be passed through the gel cap.

nal incision by slipping the flexible inner ring inside the abdomen (Figure 76.8), with the tension from the elastic sheath holding the rigid outer ring stable on the abdominal wall (Figure 76.9). The outer cap is then snapped onto the wound retractor. To use a hand intra-abdominally, it is inserted to the desired depth and the iris valve is tightened around the forearm by turning the outermost ring clockwise and fixing it in place by way of ratcheted teeth (Figure 76.10). Slight inward movements of the forearm can be made, but large movements require that the iris valve be opened a bit. Similarly, pulling back or removing the forearm necessitates tightening the valve to prevent gas leak. The valve can be

completely occluded (Figure 76.11) or it can be tightened around a port or laparoscopic instrument.

Adjuncts

Fluid can track up the intra-abdominal forearm and soak through the surgeon's gown above the glove. Double gloving does not necessarily prevent this, and some additional barrier is recommended. We have found the simplest and most effective to be a Steri-Drape™ Small Towel Drape 1000 (3M Company, St

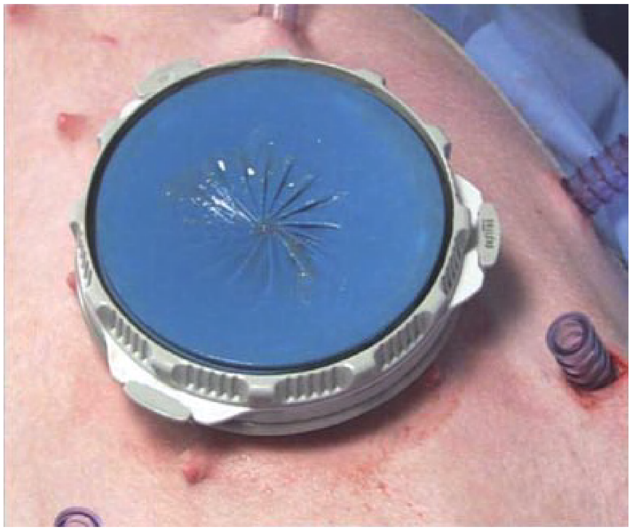

Figure 76.11 Dextrus® Access Port: the iris valve can be completely occluded (courtesy of Ethicon Endo-Surgery Cincinnati, OH, USA).

Paul, MN, USA). The adhesive strip is wrapped around the wrist and the rest of the drape trails down over the forearm, covered by a second glove over the hand and adhesive strip (Figure 76.6). The second glove should be dark to minimize glare. The Dextrus™ Access Port comes packaged with a plastic wrap that serves the same function. Other surgeons have overcome the fluid problem by using a disposable fluid-impervious gown.

Surgical instruments can be placed into the abdomen for use by the intra-abdominal hand. Small open surgical instruments, including Atson forceps and short Satinsky clamps, have been used intra-abdominally during HALS. Of these, the most useful may be hand-held bulldog clamps for temporary vascular occlusion. Additionally, there are instruments made specifically for use by the intra-abdominal hand. The Dextrus™ Finger Mounted Instruments (Ethicon Endo-surgery) fit over the index or middle finger (Figure 76.12), and include Russian forceps, locking forceps, specialty grasper, curved dissector, and spatula retractor (Figure 76.13).

General techniques for hand-assisted laparoscopy

Choice of position for surgeon, HALS device, and ports

Although the application of HALS to retroperitoneoscopic surgery has been reported, it is not a widely accepted technique. This section, pertaining to technique, will not address retroperitoneoscopic HALS, although the few reported series are included in the section on results.

Either the primary or the assistant surgeon can use their hand intra-abdominally. When the primary surgeon's hand is intra-abdominal, direct manual dissection is possible. However, the primary surgeon then has only one hand free to manipulate a laparoscopic instrument. If the assistant's hand is in the abdomen, then the primary surgeon can use two laparoscopic instruments, and the intra-abdominal hand is used primarily only for retraction. This distinction is important because it can alter port placement. Figure 76.14 indicates the most common HALS device and port arrangements for HALS renal surgery when the surgeon's hand is intra-abdominal. Figure 76.14A is the most typical arrange-

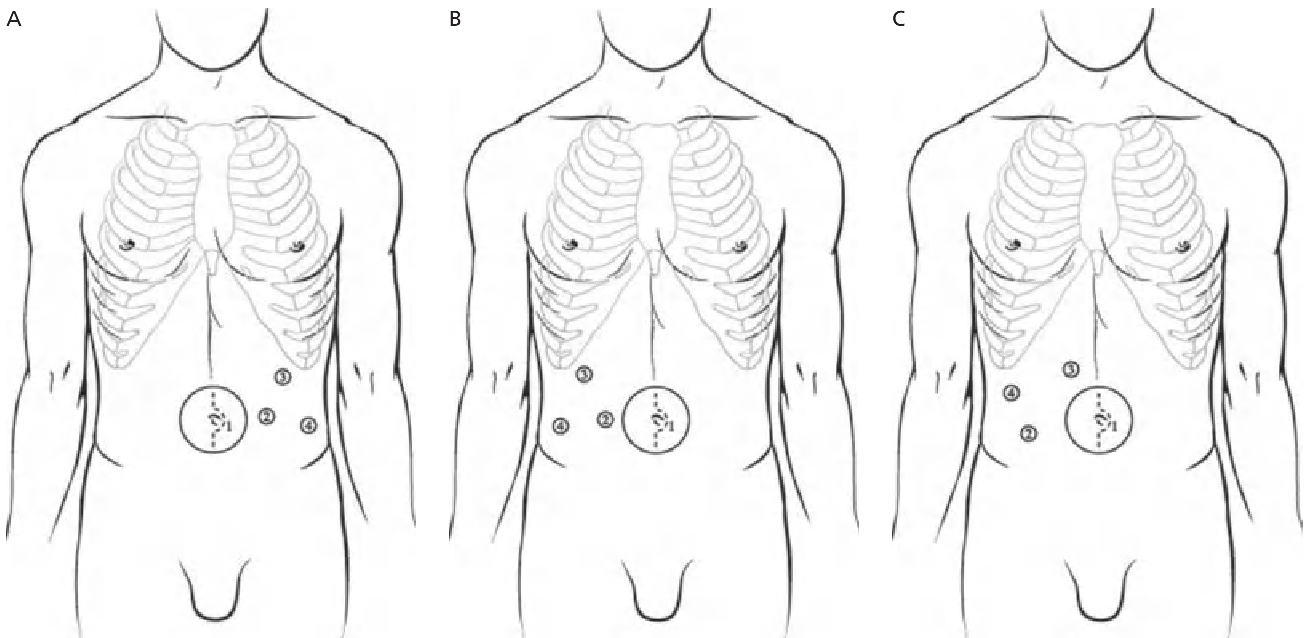

Figure 76.14 (A) Typical port placement for left hand-assisted laparoscopic surgery (HALS) nephrectomy using the surgeon's left hand in the abdomen. (B) Mirror image, for right HALS nephrectomy using the surgeon's right hand in the abdomen. (C) One alternative for right HALS nephrectomy using the surgeon's left hand in the abdomen. 1, HALS device; 2, videolaparoscope port; 3, working port for surgeon; 4, assisting port.

ment for left-sided renal surgery by a right-handed surgeon. The nondominant (left) hand is placed through the HALS device in the periumbilical midline. This allows simultaneous retraction of bowel and finger dissection of the kidney. The assistant operates the videolaparoscope through a port at the level of the umbilicus, 1–2 cm lateral to the edge of the HALS device (#2 in Figure 76.14A), and an instrument placed through a lateral assisting port (#4 in Figure 76.14A). The surgeon's working port is placed 1–2 cm below the costal margin (#3 in Figure 76.14A), on the line that extends from the videolaparoscope port to the patient's ipsilateral shoulder. There is more variation for right-sided renal surgery by a right-handed surgeon. Some, including this author, recommend an arrangement that is the mirror image of the left-sided procedure (Figure 76.14B). The right hand is used intra-abdominally, which allows retraction of the liver by the back of the hand while dissecting the kidney. The surgeon's left hand is used to manipulate laparoscopic instruments, which some right-handed surgeons find awkward. The ability to use either hand intra-abdominally is valuable, and if an "ambidextrous" approach is used when starting out with HALS, then it is quickly learned. Some portions of the procedure are facilitated by using a different hand in the abdomen, on either side, so it is helpful to be ready to use either hand intra-abdominally.

An alternative for right nephrectomy by a right-handed surgeon is depicted in Figure 76.14C. Here, the surgeon's left hand is placed through the HALS device and the right hand operates an instrument through the working port (#3 in Figure 76.14C). The assistant operates the videolaparoscope (#2) and an assisting instrument (#4). Some place the HALS device obliquely in the ipsilateral lower quadrant when using this approach. A number of HALS device placements have been described, including midline (supra-, peri-, and infra-umbilical), paramedian, subcostal, lower quadrant oblique ("muscle-splitting" Gibson incision), and transverse suprapubic (Pfannenstiel). Each will be associated with slightly different port placements, depending on whether the intra-abdominal hand is the surgeon's or assistant's, and whether the left or right hand is preferred. The general principles that guide device and port placement in HALS are: maximization of effectiveness of the hand, minimization of videolaparoscope obstruction by the hand, and centering the videolaparoscope between instruments rather than working with the hand and instruments all off to one side. Use of a 30° videolaparoscope is very useful during HALS to reduce obstruction of vision by the intra-abdominal hand.

Tips and tricks

HALS facilitates transfer of skills from open surgical to laparoscopic surgery. While this is an easier step to make than that from open surgery to standard

Figure 76.15 Insertion of a laparoscopic port directly onto the intra-abdominal hand.

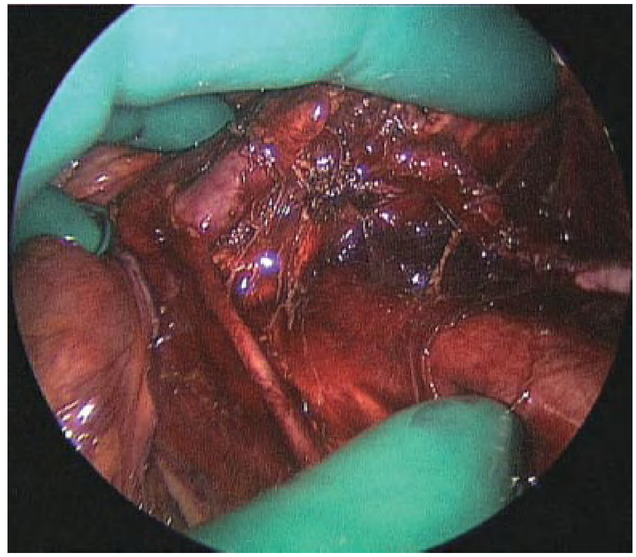

Figure 76.16 The "C" position. Left hand placed through a midline HALS incision, for left nephrectomy.

(nonhand-assisted) laparoscopic surgery, HALS does require a distinct skill set. In this section, some techniques that are different from open surgery and from standard laparoscopic surgery are highlighted.

A laparoscopic port can be inserted through both the Gelport® and the Dextrus® Access Port, and the Gelport® will accommodate several ports or a hand and additional ports. This allows inspection of the abdomen laparoscopically before port placement. Ports can be inserted under direct visualization, or a hand can be placed through the HALS device and the ports can be inserted directly onto the intra-abdominal hand (Figure 76.15). This maneuver should be performed only with noncutting trocars and only after visual inspection has confirmed the inner abdominal wall to be free of adhesions.

After placing the HALS device and ports, a laparotomy pad is placed into the abdomen. This can be used to soak up fluid and blood, either by itself (when it is not yet saturated) or by compressing it with the hand and using a laparoscopic aspirator to remove fluid through the pad. Some surgeons place a hemostat on the blue tag of the laparotomy pad to prevent its complete placement into the abdomen. We prefer to place the entire pad inside the abdomen to allow its unrestricted use, but we do cut off the blue tag and instead clamp it to the drapes as a visual reminder that a pad is inside the abdomen.

Performing multiple tasks simultaneously with the intra-abdominal hand takes greatest advantage of its presence. Retraction and exposure can be obtained in several directions at once, or the hand can simultaneously retract and dissect. One of the most useful multitasking hand positions is the "C" position (a term coined by Stephen E. Strup MD) for dissection medial to the lower pole of the kidney and at the renal hilum (Figure 76.16). Using the left hand for left renal surgery, or the right hand for right renal surgery, the forearm is placed parallel to the great vessels, palm lateral, wrist flexed 45–90°, index finger lifting the kidney, thumb exerting inferomedial traction on tissue, and the middle fingers extended. This position allows simultaneous retraction of bowel with the back of the hand, elevation of the lower pole, and dissection with the fingers. When the hand is elevating the lower pole, an irrigator–aspirator probe or some other instrument can be placed through an assisting port to help in the dissection.

When dissecting out the renal hilum, the renal artery and vein can be encircled *en bloc* with the thumb and forefinger of the intra-abdominal hand. After sharply dissecting tissue cephalad to the renal vein, it is usually easy to bluntly place the index finger cephalad to the renal vein, wiggle it in a posterior direction until the psoas muscle is touched, and then scoop inferiorly to gather up the entire renal hilum. This maneuver is safe as long as a careful touch is used, sensing resistance that indicates an early branch or an accessory vessel. Encircling the hilum in this way provides the ability to rapidly control it in case of vascular injury, and with this added confidence the subsequent hilar dissection can proceed rapidly. This maneuver is less useful if the intention is to remove the adrenal gland with the specimen (on the left side), as it is not safe to perform blunt dissection medial to the adrenal gland.

Results of hand-assisted laparoscopic surgery

Series

In urology, HALS is most commonly applied to nephrectomy. The first reported use of HALS in urology was for radical nephrectomy [4], as was the first use of a commercial HALS device in urology [8]. In one of the earliest large series of HALS for radical nephrectomy, Stifelman *et al.* reported 95 HALS radical nephrectomies for large specimens [11]. The mean operative time was 158 min and the major complication rate was only 4%, with a rate of conversion to open surgery of 3%. The oncologic efficacy of HALS radical nephrectomy has been confirmed in several series with long-term follow-up. Bandi *et al.* reported 5-year recurrence-free survival of 90% after 65 HALS radical nephrectomies with more than 3-year follow-up [12]. Harano *et al.* reported a 4-year recurrence-free survival of 88% in a series of 96 patients [13]. At the University of Michigan, the 5-year recurrence-free survival in a series of 108 patients with a mean tumor size of 6.9 cm was 82% [14]. Kawauchi *et al*. reported a 5-year recurrence-free survival of 92% among 123 patients [15]. In the largest series reported to date of HALS radical nephrectomy with long-term follow-up, a multi-institutional series from 26 centers in Korea involving 197 patients, the 5-year recurrence-free survival was 95% [16].

There have been 17 series (containing 10 or more patients) of HALS nephroureterectomy for upper tract urothelial neoplasms (not including series that have been updated by subsequent ones) published through 2009 [17–33]. In the total of 621 patients described in these series, the operative time averaged 261 min, with 7% major and 14% minor complication rates overall. Conversion to open surgery was required in only 2.5% of cases. The nonvesical recurrence rate was 11% with 23-month mean follow-up. A description of the long-term outcome of HALS nephroureterectomy for urothelial carcinoma from the University of Michigan includes 62 patients with a median follow-up of 77 months: the 5-year cancer-specific survival was 89% for low-grade disease and 72% for high-grade disease [34].

Many of the recently reported series of donor nephrectomy have been with HALS. Among the 12 such series containing 100 or more patients, reporting 2034 patients in total, the mean operative time was 182 min and the mean warm ischemia time 2.1 min [35–46]. The minor and major complication rates were 8.8% and 3.8%, respectively, with a conversion to open surgery in only 1.0% of patients. In the studies that reported convalescence, the mean time to return to nonstrenuous activity levels was 24 days. Graft function has been excellent, with 97.1% functioning at a mean follow-up of 16 months. Delayed function of the allograft occurred in 4.3% and ureteral complications occurred in 2.0%. Of the first 200 HALS donor nephrectomies performed at the University of Michigan, the ureteral complication rate has been 4% [38]. The 1-month, 1-year, and 3-year actuarial graft survival rates are 97%, 95%, and 94%, respectively.

Other reports of HALS for renal surgery include partial nephrectomy [47–51], heminephrectomy (horseshoe kidneys, duplicated upper tracts, etc.) [52–55], bilateral nephrectomy [56–64], and bilateral partial nephrectomy [65]. Bilateral nephrectomy for autosomal dominant polycystic kidney disease is particularly challenging with standard laparoscopic techniques, and is perfectly suited to HALS. Other difficult maneuvers, such as radical nephrectomy with associated excision of renal vein or vena caval thrombus [66–70], and removal of kidneys with xanthogranulomatous pyelonephritis or other inflammatory or unusual conditions [68, 71–76], are facilitated by HALS.

HALS in urology is most commonly applied to renal surgery, but there have been reports of its use for other organs as well. Similar to its use for bilateral nephrectomy, HALS facilitates multiorgan removal for other entities [77–80]. Laparoscopic adrenalectomy is usually well-performed with standard transperitoneal or retroperitoneoscopic techniques, but in cases of large specimens or as an alternative to conversion to open surgery, HALS does have a role in the management of adrenal disease [81–85]. Minimally invasive cystectomy is growing in popularity. Even when using standard or robot-assisted techniques, many surgeons prefer to create at least part of the urinary diversion via a mini-laparotomy. Given this, several groups have reported using this mini-laparotomy incision for a HALS device, and performing the cystectomy or pelvic exenteration with HALS techniques [86–91]. HALS for other procedures, such as ureterolysis [92], retroperitoneal lymph node dissection [93], and resection of local renal cell carcinoma recurrences [94], has been described.

Comparisons to other techniques

Although HALS has been reported via the retroperitoneoscopic route for renal surgery [20, 28, 31–33, 95–101], this is not yet a commonly accepted technique. As such, when assessing the role of HALS in urologic laparoscopy, this chapter considers it to be a transperitoneal approach. Transperitoneal HALS, standard transperitoneal laparoscopy, and standard retroperitoneoscopy all have advantages and disadvantages. In this section, comparisons between the techniques are presented.

Wolf *et al.* reported the initial comparison of hand-assisted and standard transperitoneal laparoscopic nephrectomy in 1998, using the first hand-assisted (n = 13) and standard (n = 8) transperitoneal laparoscopic nephrectomies performed at the University of Michigan and the University of Wisconsin [102]. The mean operative time for hand assistance was 90 min shorter than that for standard laparoscopy. This comparison suggests that early in a surgeon's experience, HALS "shortens the learning curve" for transperitoneal nephrectomy. A subsequent report from the University of Michigan made the same comparison after more experience had been gained, and revealed that after an experience of approximately 20 laparoscopic radical nephrectomies, the advantage of HALS over standard laparoscopy in terms of operative time fell to only 30 min [103].

Two meta-analyses of studies comparing HALS and standard laparoscopic approach for nephrectomy produced similar results. Kokkinos *et al.*, in their meta-analysis limited to donor nephrectomy, evaluated nine studies reporting on 376 patients [104]. They found that HALS and standard laparoscopy had similar donor and recipient complication rates, but that HALS was associated with shortened operative and warm ischemia times, as well as decreased intraoperative bleeding. Silberstein and Parsons assessed the literature 2 years later and considered all types of nephrectomies, and included 25 studies comprising 3051 patients [105]. They found that hand-assisted nephrectomy was associated with significantly less operative blood loss and decreased risk of conversion, but that there were no significant differences in operative time, length of stay, or risk of perioperative transfusion or complication.

In a randomized trial of HALS versus standard donor nephrectomy (20 in each group), Bargman *et al.* found that operative time was significantly less with the standard approach (219 vs 200 min, $P = .02$), but that there were no differences in estimated blood loss, warm ischemia time, length of postoperative stay, analgesic use, rate of complications, pain scores on postoperative day 1 and 2, or quality-of-life scores at 1 and 3 months [106]. Of note, all nephrectomies in this series were performed by a surgeon with extensive experience in both HALS and standard laparoscopy, including more than 100 laparoscopic donor nephrectomies and more than 500 other laparoscopic renal operations prior to the study period. This is consistent with the data reported above; with experience some advantages of HALS over standard laparoscopy (such as in reducing operative time) diminish.

There have been two prospective trials involving HALS for radical nephrectomy. Nadler *et al.*, in a comparison of standard transperitoneal, standard retroperitoneal, and HALS (11 in each group; not randomized but prospectively enrolled in alternating fashion) found that operative time was significantly lower in the HALS group, and that hospital stay and time to normal daily activity were significantly shorter in the standard transperitoneal group [107]. Intraoperative blood loss, postoperative narcotic use, and time to oral intake were similar in all three groups. Although there were no differences in early complications, incisional hernias occurred only in the HALS group. In a multi-institutional randomized trial comparing HALS (nine patients) versus standard transperitoneal laparoscopic (12 patients) radical nephrectomy, Venkatesh *et al.* found no differences in operative time [108].

As noted above, series of surgeons' early experience with standard laparoscopic and HALS nephrectomy often suggest an overall lower complication rate with HALS [102, 109], but as experience is gained the overall complication rates of the two approaches are similar. However, the intra-abdominal hand does appear to reduce some specific complications, in particular the need to convert to open surgery. Silberstein and Parsons found this in their meta-analysis [105]. At the University of Michigan, 196 standard laparoscopic radical nephrectomies were compared with 154 HALS radical nephrectomies [110]. There were no conversions to open surgery from HALS but conversion to open surgery occurred in the standard laparoscopic group in 0.8% of nonobese, 3.0% of obese, and 17% of morbidly obese patients. The difference was statistically significant in the latter two groups. In addition, the availability of HALS provides an alternative to conversion from standard laparoscopy to open surgery; converting to HALS from standard laparoscopy may allow the procedure to be completed in a minimally invasive fashion [111].

Conversely, some complications appear to occur more commonly in association with HALS compared to standard laparoscopy. Troxel and Das noted a 6% rate of incisional herniation at the HALS site in a series of 50 HALS radical nephrectomies [112]. Terranova *et al.* reviewed 54 patients undergoing HALS renal surgery, and reported complications related to the HALS incision in 9.3%, including infection, herniation, skin incisional breakdown, fascial dehiscence, and enterocutaneous fistula [113]. Montgomery *et al.* reviewed 424 consecutive HALS renal procedures and reported similar findings, including infection in 6.8%, incisional hernia in 3.5%, and fascial dehiscence in 0.5% of HALS incisions [114]. Although direct comparative data are limited, some reports suggest an increased wound complication rate with HALS compared to standard laparoscopy [107]. Overall, wound infections and hernias appear to occur less frequently in association with HALS than with open surgery, but more often than in association with standard laparoscopy. In one literature compilation which included 56 reports, there was a significantly

greater wound complication rate associated with HALS compared to standard laparoscopy (1.9% vs 0.2%, $P < .05$) [115].

Data comparing the duration and intensity of convalescence after HALS compared to standard laparoscopy are less consistently reported than more objective outcomes, and are subject to bias in retrospective studies. In both of the prospective trials involving HALS for radical nephrectomy described above, there was some measure of a longer and/or more intense recovery period in the HALS patients. Nadler *et al.* found the hospital stay to be 2.1 days after standard transperitoneal laparoscopy compared to 3.4 days after HALS radical nephrectomy [107]. Narcotic use tended to be less in the former group, but the difference was not significantly different. In their multi-institutional randomized trial comparing standard transperitoneal laparoscopic and HALS radical nephrectomy, Venkatesh *et al.* found a significantly longer time to return to normal activity and to work in the HALS group, although there were no differences in hospital stay or narcotic use [108]. In a retrospective but large comparison of the two approaches to radical nephrectomy (113 standard laparoscopic, 158 HALS), Matin *et al*. did find longer hospital stay (4 vs 2 days) and more narcotic use in the HALS group [116]. In another retrospective but large study (147 standard laparoscopic and 108 HALS), Gabr *et al.* found that hospital stay was longer (by a mean of 0.4 days) and time to return to nonstrenuous activity was greater (by a mean of 3.1 days) in the HALS group [110].

In addition to patient-related outcomes, HALS appears to have a distinctive surgeon-related impact. Johnson *et al.*, describing a survey of 25 urologists involved in lapararoscopic fellowship programs, reported that HALS was associated with significantly more hand/wrist, forearm, and shoulder pain compared to standard laparoscopy [117]. Conversely, there was significantly more neck pain associated with standard laparoscopy. There was no significant difference between the approaches in terms of lower back pain. Gofrit *et al.* found similar results in a survey of 73 members of the Endourology Society [118]. HALS was associated with more pain involving the fingers, hand/wrist, and forearm/elbow than standard laparoscopy, while standard laparoscopy was associated with more complaints about neck pain. There were no major differences with regards to shoulder, upper back, and lower back pain. This survey also included questions about robotic surgery. Overall, robotic surgery was associated with the fewest complaints of pain and HALS was associated with the most. The work of Ost *et al*. suggests one possible mechanism for the increased hand, wrist, and forearm pain with HALS [119]. These investigators used oxygen sensors to measure oxygen saturation in the hand during HALS nephrectomy, and found that a report of hand pain during HALS nephrectomy was associated with hypoxia of the hand, down to 56–88% local oxygen saturation.

Overall, then, published data suggest that HALS is generally faster than standard transperitoneal laparoscopy, but that the difference decreases with increasing surgeon experience. The relative impact of HALS on operative time also appears to vary with the specific procedure. For advanced procedures, HALS appears to reduce the likelihood of conversion to open surgery, and converting to HALS is a good alternative to converting to open surgery when standard laparoscopy cannot be continued. There are important disadvantages of HALS to be acknowledged. The larger incision for HALS is associated with rates of infection and herniation that probably exceed those for standard laparoscopy. The intensity and duration of postsurgical recovery is slightly greater with HALS compared to standard laparoscopy, although the magnitude of the difference between HALS and standard laparoscopy is much less than that between HALS and open surgery. Finally, the surgeon pays a price during HALS in terms of increased upper extremity pain compared to standard or robot-assisted laparoscopy.

Selective use of hand-assisted laparoscopic surgery

Table 76.1 lists the advantages and disadvantages of HALS. The relative impact of these considerations differs by surgeon and procedure. Table 76.2 suggests the general situations in which HALS is most useful. HALS is an excellent choice when intact specimen removal is required, as it takes advantage of the required incision throughout the entire procedure rather than just at the conclusion. Another major consideration is surgeon experience, with laparoscopy in general or with

Table 76.1 Advantages and disadvantages of hand-assisted laparoscopic surgery compared to standard laparoscopy.

Typical advantages
Faster
Easier
More control in operating room by surgeon
Better control of vascular injury
Reduced need for conversion to open surgery
Enhanced teaching
Typical disadvantages
Larger incision
Sometimes necessitates suboptimal port placement
Hand can get in the way
Increased wound complication rate
Slightly greater intensity and duration of convalescence
More upper extremity pain for surgeon

Table 76.2 General situations in which hand assistance is most useful.

Intact specimen removal is required
Limited experience:
• With laparoscopy in general
• With specific procedure
Difficult procedure
• Large specimen
• Reoperation
• Perihilar mass that limits access to vasculature
• Other process (inflammation, fibrosis, etc.) that render dissection difficult
Medical comorbidities necessitate rapid procedure

a new procedure. HALS is an excellent way for an inexperienced surgeon to start performing laparoscopy, or for an experienced surgeon to start performing a new procedure. Similarly, a difficult procedure is a good indication for HALS. Large specimens, reoperation, a perihilar mass, or anytime the surgical planes or tissue identification are indistinct can result in a prolonged and complication-prone laparoscopic procedure. HALS can make the difference between conversion to open surgery and completion of the minimally invasive procedure. Finally, for a patient with severe chronic obstructive pulmonary disease or congestive heart failure, in whom a rapid procedure is necessary because of problems owing to hypercapnia or elevated intra-abdominal pressure, HALS can be very useful.

With these considerations in mind, HALS is best selected when there is a clear advantage (in terms of operative time, safety, specimen manipulation, etc.) over standard laparoscopic techniques. The degree of advantage or disadvantage of HALS is determined by the individual surgeon. The best procedures for HALS are advanced extirpative renal procedures. For radical nephrectomy, HALS has most advantage when the specimen is large or the anatomy is difficult. For partial nephrectomy, HALS might facilitate accurate resection, collecting system repair, and/or hemostasis for tumors that are hard to access. For straightforward radical nephrectomies, and for partial nephrectomy for accessible tumors, standard transperitoneal or retroperitoneal techniques are effective in the hands of many. During procedures where intact specimen removal is required, such as nephroureterectomy for urothelial carcinoma or live donor nephrectomy, HALS takes advantage of the required incision throughout the entire procedure rather than just at the conclusion.

For some procedures HALS is less useful, or may even be a hindrance. Laparoscopic simple nephrectomy can be performed in a straight-forward manner with standard transperitoneal or retroperitoneal techniques unless the specimen is inflamed (i.e. pyonephrosis or xanthogranulomatous pyelonephritis) or very large (i.e. autosomal dominant polycystic kidney disease). Standard laparoscopic techniques are also adequate for renal cyst resection and adrenalectomy in most cases. For reconstructive procedures such as laparoscopic pyeloplasty or nephropexy, there is little advantage to HALS. Although there has been some interest in HALS for pelvic procedures, most urologists use a standard or robot-assisted laparoscopic approach to minimally invasive pelvic surgery.

Conclusions

HALS is technically easier than standard laparoscopy, with a "shorter learning curve" for most procedures. The current devices are easily applied and effective. Although there is considerable variation in port placement, especially with regards to right nephrectomy for right-handed surgeons, the general techniques are standardized. Unless there is extensive laparoscopic experience, HALS offers more rapid operating times and a tendency towards lower need for conversion to open surgery than standard laparoscopy for most extirpative renal procedures. These advantages come at the price to the patient of slightly greater intensity and duration of convalescence, and an increased wound complication rate, compared to standard laparoscopy. The surgeon is at greater risk of suffering upper extremity pain. Given prior experience, HALS offers minimal if any improvement over standard laparoscopy for straightforward renal procedures, reconstructive procedures, and most pelvic procedures. HALS is most useful for difficult extirpative laparoscopic procedures, and when intact extraction is desired.

CHAPTER 77
Pelvic Lymphadenectomy

Steven M. Lucas[1] & Chandru P. Sundaram[2]

[2]Indiana University School of Medicine, Indianapolis, IN, USA

Introduction

Schuessler *et al.* first reported laparoscopic pelvic lymph node dissection (LPLND) for staging of prostate cancer in 1991 [1]. In the early 1990s LPLND was the most frequently performed urologic laparoscopic surgery. With stage migration in prostate cancer observed with widespread screening of patients, LPLND is frequently performed with a radical prostatectomy or, more recently, with cystectomy. The operation provides useful information in a patient with prostate or bladder cancer where pathologic involvement of the pelvic lymph nodes will alter definitive management of the malignancy. Today, although LPLND is most commonly performed for the surgical staging of prostate cancer, indications for an extended version of this staging modality are malignancy of the bladder, urethra, and penis, where confirmation of nodal metastases can significantly alter management.

For patients with urologic pelvic malignancy, the status of the pelvic lymph nodes will have a major impact on prognosis, as well as the determination of appropriate therapeutic intervention. It is generally agreed that any significant lymphatic dissemination of malignancy in a patient with neoplastic disease involving the prostate, urethra, or penis is a sign that the cancer is most likely incurable in most patients. Similarly, the detection of positive pelvic lymph nodes in patients with transitional cell carcinoma (TCC) of the bladder is a poor prognostic finding that should suggest the need for chemotherapy. LPLND can provide important prognostic and therapeutic benefit in the treatment of neoplasms. This underscores the importance of obtaining accurate histopathologic staging information prior to developing a treatment plan.

In the past, attempts at detecting pelvic lymphatic metastases using noninvasive diagnostic modalities, such as computed tomography (CT), magnetic resonance imaging (MRI), and pelvic lymphangiography, have been unsatisfactory as a result of unacceptably low sensitivity and specificity, though these are improving with newer detection techniques [2, 3]. Ultrasound- and CT-guided transcutaneous fine-needle aspiration biopsy (FNAB) can be effective when evaluating enlarged pelvic lymph nodes. Unfortunately, the latter two interventions are highly operator dependent, and in the absence of gross lymphadenopathy are incapable of determining the presence of micrometastasis following early dissemination of malignancy. Therefore, PLND remains the gold standard for accurate staging of patients with urologic pelvic malignancy.

Recent lymph node mapping series suggest that some patients may benefit from a more aggressive lymph node dissection [4, 5]. Patients with an increased risk of lymph node metasasis of prostate cancer may be understaged with a limited lymph node dissection [5–10]. In bladder cancer, an extended lymph node dissection increases the rate of detection of positive lymph nodes in several series, providing valuable treatment information [11–13]. In both patients with and without node-positive disease, an extended lymphadenectomy may even provide a survival benefit [12–15].

Smith's Textbook of Endourology, Third Edition. Edited by Arthur D. Smith, Gopal H. Badlani, Glenn M. Preminger, Louis R. Kavoussi.

Since lymphatic metastasis from primary malignancy involving the prostate and other pelvic organs will have major prognostic and therapeutic implications, the minimally invasive nature of LPLND to detect disseminated and probably incurable disease could potentially circumvent the unnecessary morbidity associated with unsuccessful radical therapy. More often the urologist performs these dissections as part of a larger surgery intended to remove the cancer. With the increase in laparoscopic and robotic prostatectomy and cystectomy, the need to perform an adequate minimally invasive lymphadenectomy has grown. In recent series, the lymph node yield of minimally invasive lymphadenectomy is comparable to that of open lymphadenectomy [16, 17].

In this chapter we review the indications and techniques for minimally invasive pelvic lymphadenectomy.

Indications

Adenocarcinoma of the prostate

In a landmark study in 1959 that evaluated the common lymphatic pathways by which metastatic adenocarcinoma of the prostate spreads, Flocks *et al*. clearly demonstrated a direct correlation between the clinical stage of disease and an increased likelihood of lymphatic metastasis [18]. This was especially true in patients in whom periprostatic extension involved the seminal vesicles; pelvic lymph node metastasis was noted in 50–80% of patients under these circumstances.

Similarly, elevation of serum tumor markers, including enzymatic prostatic acid phosphatase (PAP) and prostate-specific antigen (PSA), may suggest an increased likelihood of lymph node involvement. Stamey and Kabalin have demonstrated a strong correlation between advanced pathologic stage and increasing serum PSA [19]. Similarly, Lange *et al*. and Hudson *et al*. reported studies in 1989 that focused on the correlation between serum PSA and pathologic stage [20, 21]. Based on an analysis of data culled from several studies, Lange *et al*. reported a 65% likelihood of seminal vesicle or lymph node involvement in patients with a preoperative PSA value between 20 and 50 ng/mL (Hybritech assay) [20].

Preoperative prediction nomograms have been developed in an attempt to help guide physicians on which patients are at risk for lymph node involvement. The Partin and Kattan nomograms have 80% accuracy in predicting lymph node metastases [22, 23]. The widespread acceptance of these nomograms is reflected in the 2009 National Comprehensive Cancer Network guidelines which state that patients with a less than 7% risk of lymph node metastasis can forego a formal lymph node dissection [24]. However, these nomograms rely heavily on PSA, biopsy Gleason score, and clinical stage.

Until recently imaging techniques, either CT or MRI, have yielded a 35% sensitivity for detecting lymph node invasion, primarily due to stage migration of prostate cancer, making micrometastases in lymph nodes more prevalent than gross metastases [25, 26]. Pelvic MRI using an endorectal coil may help in detecting smaller lymph node metastases. New innovations utilizing lymphotropic agents, such as paramagnetic iron-oxide nanoparticles and ferumoxtran-10, can increase the sensitivity and specificty to 80–90% and 96–98%, respectively [27, 28]. Additionally, improvements in serum tumor markers have improved the ability to preoperatively predict lymph node invasion. For example, endoglin, a cell-surface protein located in endothelial cells, demonstrated a 98% accuracy in predicting lymph node involvement when combined with clinical stage, biopsy Gleason score, and PSA [29].

Although these important studies have greatly increased the urologist's ability to predict the extent of disease in patients with prostate cancer, the associations are by no means absolute. Unfortunately, the relationship between serum tumor markers and actual pathologic stage is not clear cut. A markedly elevated PSA level is strongly indicative of advanced disease, whereas a PSA of less than 10 ng/mL suggests early local disease. However, to rely on these values alone may lead to an under- or over-staging of prostate cancer , resulting in erroneous therapeutic intervention and unwarranted morbidity with no clinical improvement in the patient's outcome [30]. Furthermore, newer predictive modalities require further investigation to determine their relationship to the clinical outcome of disease. They are also limited in the validation of pathology of the tissue obtained during the PLND, for which there are several variations in the template for dissection. For this reason, histopathologic evaluation of the pelvic lymph node specimen remains the gold standard for making therapeutic decisions [31].

Prognostic and therapeutic impact in prostate cancer

Patients identified to have positive lymph nodes at the time of radical prostatectomy have demonstrated a worse prognosis than those who are not. In a series of over 1400 patients treated with laparoscopic prostatectomy, Touijer *et al*. found a 78% overall 5-year progression-free probability for all risk groups of prostate cancer versus only a 49% 3-year progression-free probability in lymph node-positive patients, where all patients demonstrated a clinical recurrence within 5 years [32]. In a series of 143 node-positive patients, Palapattu *et al*. noted a 17% PSA progression-free rate at

7 years of follow-up [33]. More specifically, a combined series of 703 lymph node-positive patients following radical prostatectomy with extended PLND demonstated that patients with two or fewer positive lymph nodes demonstrated an improved cancer-specific survival relative to those with more than two positive lymph nodes (84% vs 62% at 15-year follow-up). Patients with more than two positive lymph nodes were 1.9 times more likely to die from prostate cancer [34].

Identification of patients with positive lymph nodes provides prognostic information that is useful in counseling and monitoring patients. It also has the potential to identify high-risk patients who may benefit from adjuvant or salvage therapy. In a retrospective review of 250 consecutive patients with positive lymph nodes, salvage radiation therapy was associated with a hazard ratio (HR) of 0.38, relative to those receiving postoperative hormone therapy alone in multivariate analysis [35]. This result, however, is controversial and requires corroboration in additional studies.

It is also controversial whether pelvic lymphadenectomy can provide a therapuetic benefit in prostate cancer. In a review of 13 000 prostatectomies contained in the Surveillance, Epidemiology, and End Results (SEER) database, pelvic lymphadenectomy was performed in 71% of patients. Cancer-specific mortality decreased in patients in whom more than four lymph nodes were removed (HR 0.77). Furthermore, if more than 10 lymph nodes were removed, cancer-specific mortality also decreased in patients who had negative lymph nodes (HR 0.89) [7]. Similarly, in over 5000 patients reviewed in another series, lymphadenectomy in patients with node-negative disease correlated with a decreased rate of biochemical recurrence [9]. Finally, in 274 T3 patients, 13% of those initially thought to be node negative harbored micrometases and developed recurrence at a rate similar to those with initially diagnosed positive lymph nodes [9].

Although these studies suggest an oncologic benefit of lymphadenectomy for both lymph node-positive and -negative disease, it is unclear whether, by taking an increased number of lymph nodes, the perceived benefit was artificially increased by identifying a lower risk group of lymph node-positive patients and removing more false-negative patients in the negative lymph node patients. In contrast to these studies, two studies found no relationship between lymphadenectomy and patient survival. In 336 low-risk prostate cancers, omission of PLND did not affect biochemical recurrence at 6 years [36]. In over 7000 patients at the Mayo Clinic with a median of nine lymph nodes removed, there was no association between the number of lymph nodes removed and PSA recurrence, systemic progression, or prostate cancer death [37]. Future studies will be needed to determine the effect of lymphadenectomy on prostate cancer outcome.

It has been previously thought that LPLND is most useful in a patient in whom metastatic prostate cancer is detected as this avoids the morbidity of treatment for presumed localized prostate cancer. Conversely, patients who undergo LPLND and do not have nodal metastases have had an unnescessary procedure. Wolf *et al*. used cost and patient preference endpoints in a decision-analysis model, and determined that LPLND before intended radical retropubic prostatectomy was beneficial only in patients with at least a 39% risk of lymph node metastases [38]. More recently, a series by Engel *et al.* challenged the notion that prostatectomy should be avoided in lymph node-positive patients. Among 1400 lymph node-positive patients in a retrospecitve review, those who underwent a radical prostatectomy had an overall survival at 5 and 10 years that was superior to that for patients who did not undergo prostatectomy (84% and 64% vs 60% and 28%). Although there were fewer patients in the prostatectomy group with four or more positive lymph nodes (17% vs 28%), the survival benefit of a radical prostatectomy persisted in a multivariate analysis (HR 2.01), which was independent of the number of positive lymph nodes [34].

Obvious nodal involvement portends poor prognosis following radiotherapy. However, the benefit of LPLND before radiotherapy is not clear. Gerber *et al.* compared the outcome of 31 men with localized prostate cancer and negative LPLND with 42 men with localized prostate cancer who underwent radiotherapy without lymph node dissection. There was no significant difference in follow-up PSAs or development of skeletal metastases between the two groups after controlling for PSA levels, Gleason scores, and clinical stage [39].

Limited versus extended lymphadenectomy

Before 1980 the surgical staging of prostate cancer included a lymph node dissection of all fibrofatty lymph node-bearing tissue within the space bounded by the genitofemoral nerve laterally, the common iliac vessels proximally, and Cloquet's node distally. This extensive lymphadenectomy effectively removed the common and external iliac, hypogastric, and obturator lymph node groups. Unfortunately, the extent of this dissection led to an early complication rate of 12–24%, with patients experiencing lymphocele formation, lymphedema, and thromboembolic phenomena [40]. Over the last 20 years a less extensive lymphadenectomy has been advocated. This modification in the margins of dissection was based on the knowledge that 85–95% of lymph node positivity in patients with lymph node metastases was found within the obturator–hypogastric node packets. Furthermore, the incidence of so-called metasatic skip

lesions, which bypass the primary obturator–hypogastric landing zones to involve the more proximal iliac or aortic chains, was reported to be only 6–14% [41, 42]. These findings have led to the standardization of obturator–hypogastric lymphadenectomy as an acceptable procedure for the pathologic staging of patients with prostate cancer.

Currently, much of the debate over PLND in prostate cancer concerns when to do a limited or extended template. The limited template typically is bounded by the medial surface of the external iliac artery anteriorly and the obturator nerve posteriorly. Extended lymph node dissection involves removal of the lymph nodes from the lateral surface of the external iliac artery to the medial surface of the hypogastric artery, extending distally to the origin of the circumflex iliac vessels. There is some variability as to the proximal extent, but it should at least include the bifurcation of the iliac artery, and in some reports includes more of the common iliac nodes (Figure 77.1). Clark *et al.* from Vanderbilt University randomized 123 patients undergoing radical prostatectomy to an extended node dissection on the right versus the left side of the pelvis, with a limited dissection on the other side. The limited dissection only included nodes along the external iliac vein and the obturator nerve. Pelvic nodal metastases were found in eight patients (6.5%). Positive nodes were found in four patients on the side of the extended dissection, in three patients on the side of the limited dissection, and on both sides in one patient. They concluded that extended node dissection in patients undergoing radical prostatectomy identifies few patients with nodal involvement who are not detected by a limited dissection. Complications, which included lymphocele in four patients, lower extremity edema in five, deep venous thrombosis in two, and ureteral injury and pelvic abscess in one each, occurred three times more often on the side of the extended dissection. However, this was a group of patients with a low probability for nodal metastases [43].

The low risk of positive lymph nodes in patients with low-risk prostate cancer (PSA ≤10 ng/mL, Gleason score ≤6, and stage T1c) has been corroborated in other series [44]. With limited lymph node dissection, the incidence of positive lymph nodes did not exceed 1%. Similarly, in series with extended lymph node dissection, the incidence does not exceed 8% for these patients [45]. Thus, the available prostate cancer guidelines do not routinely recommend staging PLND in patients within this low-risk category. This is supported by studies that fail to demonstrate a survival benefit with PLND in these patients [36, 37]. However, these survival studies are based on limited PLND and have a very low death rate overall, which makes comparison difficult.

Recent studies that include a greater number of intermediate- and high-risk prostate cancers suggest that positive lymph nodes can be missed by limitedPLND. In a study of 365 patients who underwent meticulous lymph node dissection along the external iliac vein, the obturator nerve and the hypogastric vessels during an open radical retropubic prostatectomy, positive lymph nodes were found in the nodes along the hypogastric artery in 58% of patients and exclusively at that site in 19% [46]. Eden *et al.* reviewed 374 patients who underwent PLND for PSA of 10 ng/mL or greater or Gleason score of 8 or greater, of which 253 had limited PLND and 121 had an extended lymphadenectomy. Median lymph node removal by a more limited approach (labeled standard in this series) yielded 6.1 nodes versus the extended approach which yielded 17.5 nodes. The limited template had a 0.4% positive lymph node rate, while the extended template had a 5% positive rate [6].

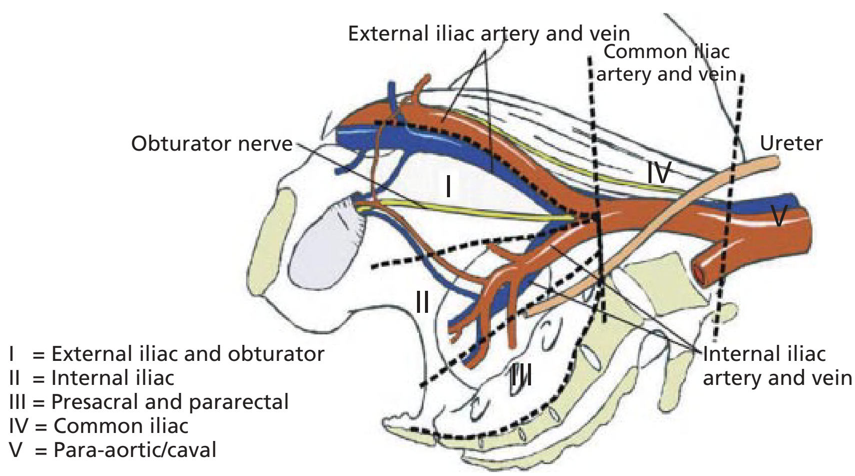

Figure 77.1 Lateral view of the pelvic wall shows the regions for pelvic lymph node dissection (reproduced from Mattei *et al.* [5], with permission).

In a series of 32 patients undergoing robotic extended PLND, a median of 18 nodes were removed, and positve nodes were found in 13% of patients [47]. In a series of 163 patients, Polcari *et al.* demonstrated an increase in median node removal and postive lymph node rate with the extended template (14.8 nodes, 18.6%) relative to standard templates performed robotically (8.2 nodes, 3.3%) or in an open fashion (7.6 nodes, 1.6%). Furthermore, the rate of postive lymph nodes increased with Gleason score: 0% for Gleason 6, 7% for Gleason 7, and 24% for Gleason 8 or higher [16]. Among the currently available guidelines for prostate cancer, the European Association of Urology and the National Comprehensive Cancer Network indicate that the use of an extended template is needed for higher risk prostate cancers. The American Urological Association (AUA) also indicates PLND for these patients, but does not specify the template [24].

As was previously suggested, the likelihood of encountering lymphatic metastasis in patients with low-stage/low-grade disease (T1a, T1c, T2a, and/or well-differentiated) is low. In this cohort, if surgical intervention is elected, it is generally considered appropriate to proceed directly to radical retropubic prostatectomy with concomitant PLND. Alternatively, if radical prostatectomy is considered, the minimally invasive nature of LPLND makes it the ideal procedure if pathologic staging is warranted based on preoperative physical examination and laboratory evaluation.

Patients who may be considered for LPLND before definitive treatment of prostate cancer include:
- Clinical stage T2b or higher;
- Gleason scores of greater than 7;
- Serum PSA of ≥20 ng/mL (Hybritech assay);
- Positive seminal vesicle biopsy (T3c);
- Enlarged lymph nodes on pelvic imaging, when percutaneous biopsy was not possible.

As will be discussed later in this chapter, a more extensive pelvic lymphadenectomy is appropriate for staging cancers involving primary sites with a more proximal lymphatic drainage. Although extended lymphadenectomy is usually advocated for the pathologic staging of neoplasia arising in the urinary bladder, urethra, or penis, there are certain clinical situations in which extensive lymph node dissection is also advisable in men with prostate cancer.

Patients with a profoundly elevated serum PSA (≥20 ng/mL) are at an increased risk of demonstrating advanced disease. In these patient cohorts a negative intraoperative histopathologic evaluation of obturator lymph node frozen sections should alert the urologist to the possibility that "skip lesions" involving more proximal lymph node chains may be present. In such instances where clinical and laboratory evidence strongly suggest advanced prostate cancer, but frozen section pathologic studies show the obturator lymph nodes are free of metastatic disease, extended LPLND may be considered.

Carcinoma of the urinary bladder

It has been demonstrated that the perioperative morbidity and mortality following radical cystectomy with concomitant pelvic lymphadenectomy does not significantly differ from that of cystectomy alone. However, this radical approach may improve the accuracy of staging and potentially increase the survival of patients demonstrating micrometastatic nodal disease [48–52]

If during radical cystectomy intraoperative frozen-section evaluation reveals extensive lymphatic metastasis from primary TCC of the bladder, it is advocated that the procedure be terminated and chemotherapy intiated. Similarly, in a patient with lymphatic dissemination of adenocarcinoma or squamous cell carcinoma of the urinary bladder, extirpative surgery is unlikely to have any curative potential. For these reasons, the lymph node status of patients with primary cancer of the urinary bladder can be a major determinant in selecting the optimal therapeutic approach for each individual [40, 48–51].

The urinary bladder has a more proximal primary lymphatic drainage route than the prostate. Thus, standard and extended lymphadenectomy in bladder cancer extend more proximally than those for prostate cancer. At the minimum, Mills *et al.* describe standard lymphadenectomy to include the internal iliac, presacral, obturator, external iliac, and distal common iliac nodes [53]. The boundaries of extended lymph node extension, as defined by Stein *et al.*, include the lymph nodes bound by the node of Cloquet distally, hypogastric vessels posteriorly, the genitofemoral nerve anterolaterally, and the aortic bifurcation proximally [53]. Some describe this extension as far proximal as to the level of the inferior mesenteric vessel, which includes some paracaval and aortic nodes. Recent mapping studies of lymph node metastases during radical cystectomy support an extended dissection. Vazina *et al.* reviewed 43 patients with lymph node metastasis among 176 consecutive patients undergoing radical cystectomy with extended pelvic lymphadenectomy, in which a median of 25 lymph nodes were removed. In pT1 patients, there was one lymph node metastasis, which was in the pelvic lymph nodes. In pT2 patients, two (3%) had postive lymph nodes outside of the pelvis, while four (16%) pT3 patients had metastasis at or above the common iliacs [4]. In a multicenter review, Leissner *et al.* reported a 27.9% positive lymph node detection rate in 290 radical cystectomies with extendedPLND. Of these patients, 20 had pelvic metastasis only in the pelvis, 20 had lymph node metastasis only in the region between the common

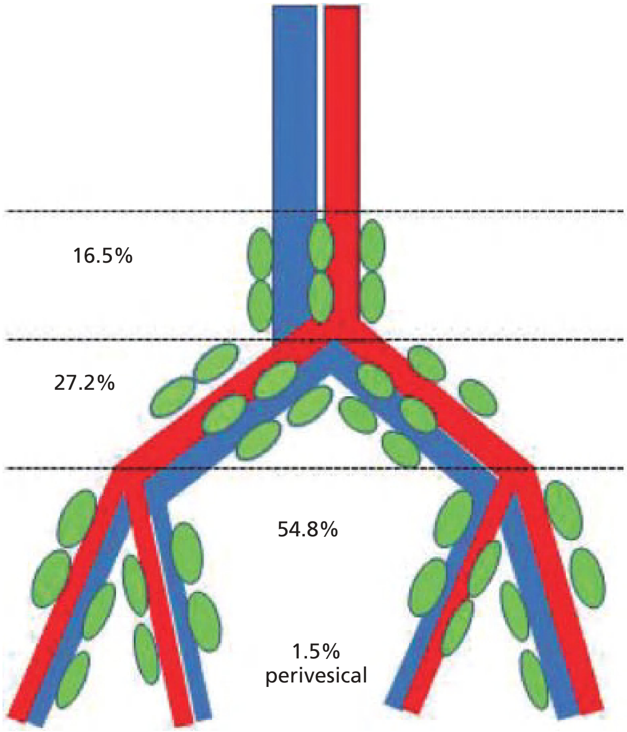

Figure 77.2 Lymphatic drainage levels for bladder cancer. A significant proportion of lymph node metastases present at the level of the common iliacs and bifurcation of the aorta as the only region of metastasis. Lymph node metastases proximal to the bifurcation of the aorta are nearly always found in the presence of more distal lymph node metastases (reproduced from Leissner *et al*. [54], with permission.

iliac and aortic bifurcations (including the presacral nodes), and none had metastasis located only above the aortic bifurcation. However, 16.5% of nodal metastases were located above the aortic bifurcation (Figure 77.2) [54] In the mapping series there were very few reported skip lesions appearing in the para-aortic region without appearing in the more distal regions [55, 56]. Thus, lymphadenectomy is necessary at least up to the point where the ureters cross the common iliac arteries, but bladder cancer probably warrants dissection up to the aortic bifurcation.

In terms of prognostic significance, pelvic lymphadenectomy in the setting of bladder cancer provides strong predictive evidence. Positive lymph nodes at the time of radical cystectomy were found in 67% of 130 pelvic recurrences reported by Dhar *et al* [14], and 128 of the patients with pelvic recurrences died within a median of 4.9 months following the recurrence. The number of positive lymph nodes also has prognostic significance with different series reporting cut-offs of five, six, and eight positive lymph nodes [57–59]. Additionally, the number of lymph nodes removed may provide separate outcomes, ranging from nine to 25 as cut-off values [15]. Lymph node density has been reported in several series to have strong prognostic information. In a review of 10 studies, reporting on 2000 unique patients, the cut-off for lymph node density ranged from 10% to 25%, with most using 20% as a cut-off. Five-year recurrence-free survival for patients with a density less than 20% was approximately 40% versus 15% in those who had a density greater than 20% [60]. Finally, extracapsular extension of the lymph nodes provided the strongest negative predictor in a series of 101 lymph node-positive patients reported by Fleischman *et al.*, with a median overall survival of 16 months compared to 60 months for patients without extranodal extension [61].

In addition to its prognostic utility, PLND may also impact the survival of patients undergoing radical cystectomy for bladder cancer. There have been reports demonstrating that a proportion of patients with grossly node-positive bladder cancer can be cured with radical cystectomy and an extendedPLND [62]. In a study of 84 patients with grossly node-positive bladder cancer (N2–3) who underwent cystectomy and extended PLND, 24% survived with a follow-up of up to 10 years [63].

Leissner *et al.* reported improved recurrence-free survival at 5 years in both lymph node-negative patients with more than 16 lymph nodes removed (organ confined: 85% vs 63%; pT3: 55% vs 40%) and lymph node-positive patients with five or fewer positive lymph nodes (53% vs 25%) [54]. Corroborating the benefit in node-negative, organ-confined patients, Poulsen *et al.* reported a 90% recurrence-free survival in patients receiving extended lymphadenectomy versus 71% in those treated with standard lymphadenectomy [64]. More recently, Dhar *et al.* compared over 300 extended and 300 limited lymphadenectomies, and reported improved survival rates in patients with and without positive lymph nodes in both organ-confined and pT3 disease [14]. Fang *et al.* demonstrated improved outcomes by instituting a minimum 16 lymph node policy on radical cystectomy patients. They compared outcomes over 4 years with the policy against 4 years prior to the policy. With the policy in place, the proportion of cases with 16 or more nodes removed increased from 42.9% to 69.3%, lymph node density less than 20% increased from 43.9% to 65.5%, and overall survival increased from 41.5% to 72.3% [12]. Although several studies suggest an improvement in survival with removal of a larger number of nodes, it is not clear how much of this benefit is due to selection bias. In patients who are deemed node negative in survival analyses, the number of patients who are falsely deemed node negative is reduced by increasing the number of nodes removed. Furthermore, in patients with node-positive disease, more patients with a very small amount of lymph node-positive disease are included in the survival analyses of those with extended lymphadenec-

tomy, leading to an increased survival in the lymph node-positve patients. Also complicating the analysis of lymph node removal is the variability in processing or counting lymph nodes that have been removed. It has been previously demonstrated that lymph node counts increase when the specimen is submitted as separate packets rather than as one *en bloc* specimen [65].

Extended LPLND in patients with TCC of the bladder is therefore likely to be indicated in patients undergoing laparoscopic or robotic cystectomy [66, 67]. Recent series of laparoscopic and robotic cystectomy demonstrate node yields that are similar to those for open PLND. In a review of 278 patients in 12 separate series of robotic cystectomy and pelvic lymphadenectomy, the mean number of lymph nodes removed in series with more than 10 patients ranged from 13 to 25 lymph nodes [68]. In another series, 30 patients undergoing laparoscopic cystectomy with pelvic lymphadenectomy yielded a similar number of lymph nodes as 35 open cystectomies (12 vs 14 lymph nodes, $P = .410$) [69]. Although current comparison of these minimally invasive techniques to open lymphadenectomy are limited, experience with these will likely increase, allowing for a more complete comparison.

Cancer of the urethra

Although exceedingly rare, isolated carcinoma of the urethra is the only urologic cancer more commonly seen in the female population [70]. Tumors involving the distal urethra generally metastasize to the superficial and deep inguinal nodes. More proximal urethral lesions metastasize first to the external and internal iliac, as well as the obturator lymph node chains, although some overlap of the respective drainage fields is not unusual. In several series, lymphatic involvement at initial presentation was as high as 35–50%, foreshadowing a bleak prognosis for patients with this disease. In 80–96% of cases in which palpable inguinal lymphadenopathy was found at the initial assessment, the disease had already metastasized [71].

Because of the rarity of this disease, the management approaches remain the subject of debate among members of the urologic community. As with other genitourinary malignancies, radical exenterative surgery is not indicated in patients with evidence of metastatic urethral carcinoma as the disease course will not be improved and the prognosis at this stage is grim. Extended LPLND may be considered in a select group of patients:

- Present with rRadiologic evidence of pelvic lymphadenopathy that is not accessible to percutaneous needle biopsy;
- Female patients with locally invasive distal lesions (muscle or periurethral tissue invasion) in the face of positive inguinal lymph nodes based on FNAB findings. Those being considered for radiotherapy as a primary modality for urethral cancer.

Cancer of the penis

The superficial and deep inguinal lymph node chains provide the lymphatic drainage for the skin (including the prepuce and frenulum) and subcutaneous tissues of the penis. The corpora cavernosa and spongiosum, urethra, and glans penis drain primarily into the external iliac nodes via the deep inguinal lymphatic chain [72]. In 25% of cases, palpable inguinal lymphadenopathy harboring metastatic disease is present at the time of initial presentation. Pathologic evaluation of bilateral inguinal lymph node dissection specimens from patients presenting with nonpalpable nodes reveals an additional 12–20% of patients with metastatic disease at the time of presentation [73, 74].

The 5-year survival rate of patients with inguinal lymph node metastases who are left untreated is roughly 19%. The prognosis is improved to an approximately 45% 5-year survival rate if an early bilateral ilioinguinal lymphadenectomy is performed, and as high as 84% in patients with microscopic-only positive lymph nodes undergoing early inguinal lymph node dissection (ILND) [75, 76]. This signifies the possibility of surgical cure even in the face of early disseminated disease. Unfortunately, this procedure is not without significant risk. A review of recent series of ILND totaling 390 patients demonstrated a major complication rate ranging from 5% to 37.5% [77]. While imaging studies have poor sensitivity in detecting pelvic lymph node metastases, pathologic information obtained from inguinal lymph nodes can identify patients at increased risk. Patients with extranodal extension, high-grade disease in the lymph nodes, or more than two involved lymph nodes are at increased risk of having positive pelvic lymph nodes [78, 79].

Tumor metastases found within the iliac (or more proximal) lymph nodes are associated with an exceedingly dismal prognosis. In a review of 128 patients undergoing ILND, overall survival at 5 years of patients with positive nodes in the inguinal region only was 64.1%. In contrast, all 21 patients with positive pelvic lymph nodes died within 3 years [79]. Given this dismal prognosis, Mukamel *et al*. recommend that bilateral pelvic lymphadenectomy should be the initial pathologic staging procedure for patients with penile cancer [2]. They described an extended dissection encompassing the removal of all lymphatic tissue from the femoral canal to the bifurcation of the iliac vessels. The boundaries of lymphadenectomy are similar to the dissection with bladder cancer. However, more distal lymphatic dissection should include the perivascular lymphatics overlying the pubic bone and underneath the inguinal

ligament [80]. Pelvic lymph node positivity revealed during this procedure would obviate the need for subjecting the patient to the attendant morbidity and mortality of groin dissection, as the probability of obtaining a surgical cure at this point is essentially zero. The therapeutic benefit of complete pelvic lymphadenectomy has not been established. It can, however, provide useful staging information that can identify patients for additional therapy. However, in the event that the pelvic lymphadenectomy reveals no metastasis in the excised tissue, ILND is recommended. For the initial staging of patients with carcinoma of the penis, we recommend extended LPLND in patients with increased risk of pelvic lymph nodal metastases. Risk factors include extensive inguinal nodal involvement, CT evidence of pelvic lymphadenoapathy that is inaccessible to needle biopsy/aspiration cytology, and a high-grade or -stage invasive primary neoplasm. It can be performed with the inguinal lymphadenectomy or it can be staged, depending upon the likelihood and extent of pelvic and inguinal lymph nodal involvement. Furthermore, it is suggested that the dissection is first made on the side ipsilateral to the penile lesion so that an intraoperative frozen-section pathologic evaluation of all lymphatic tissue specimens can be performed. Dissection of the contralateral side would be deemed unnecessary in the event of ipsilateral lymph node positivity.

Surgical anatomy

The parietal peritoneum covers the structures of the pelvis and forms ligaments and folds that are recognized during laparoscopy [81]. The median umbilical ligament is in the midline and extends from the dome of the bladder to the umbilicus. It contains the obliterated remnant of the urachus. Occasionally this may be patent or form cysts. The medial umbilical ligaments are formed by the obliterated umbilical arteries that originate from the internal iliac arteries. The lateral umbilical ligaments overlie the inferior epigastric vessels.

The gonadal vessels from the lateral aspect and the vas deferens or the round ligament (in females) from the medial aspect converge at the internal inguinal ring. The femoral canal may be visible medial to the external iliac vein. The iliac vessels are exposed upon incision of the peritoneum proximal to where the vas deferens or round ligament encounters the medial umbilical ligament. The common iliac arteries bifurcate into the external and internal iliac arteries about the level of the sacroiliac joint. The external iliac artery exits through the femoral canal to form the femoral artery. The internal iliac artery (hypogastric artery) supplies the pelvic viscera through branches: superior vesical artery, inferior vesical artery, middle rectal, uterine and vaginal arteries in the female, and obturator arteries. The external iliac vein runs medial and posterior to the external iliac artery.

The ureter crosses the iliac vessels in the region of the bifurcation of the iliac artrery. The ureter proceeds medially to the trigone of the bladder posterior to the vas deferens. In the female, the ureter forms the posterior boundary of a shallow depression, named the ovarian fossa, in which the ovary is situated. The vas deferens runs medially from the internal inguinal ring, crossing the external iliac vessels. In the female the round ligament is a homologous structure that runs from the internal ring to the uterus.

The obturator nerve emerges from the medial border of the psoas muscle at the brim of the pelvis, runs along the lateral wall of the pelvis, above the obturator vessels, to the upper part of the obturator foramen, where it enters the thigh. It runs posterior to the iliac vessels close to the bifurcation. The obturator nerve distributes muscular branches to the adductor muscles. The genitofemoral nerve runs on the psoas major muscle in the retroperitoneum medial to the gonadal vessels. It divides into the genital and femoral braches. The genital branch descends on the external iliac artery and passes through the internal ring along the back of the spermatic cord to supply the cremasteric muscle in the male. The femoral branch passes along the inner margin of the psoas muscle beneath the inguinal ligament and is distributed to the upper and anterior aspect of the thigh (Figure 77.3).

The pelvic lymph nodes and lymphatics parallel the vessels after which they are named. The obturator nodes lie along the pelvic side wall adjacent to the obturator nerve. The external and internal iliac nodes drain into the common iliac nodes, which communicate with the presacral nodes and drain into the paraortic nodes. There is also some secondary convergence of the pelvic nodes to the deep inguinal nodes and the femoral nodes.

The anatomic basis for the LPLND follows the lymphatic drainage of the prostate:

- Primary echelon: obturator, hypogastric, external iliac;
- Secondary echelon: presciatic, presacral, distal common iliac;
- Tertiary echelon: proximal common iliac, aortic.

Informed consent

Potential major complications to be discussed include vascular injury causing severe hemorrhage necessitating emergency transfusion or open exploration, and visceral injury including bowel, bladder, and ureteral injury that may require open repair. The potential dangers of CO_2 insufflation should also be discussed: hypercapnia resulting in cardiopulmonary embarass-

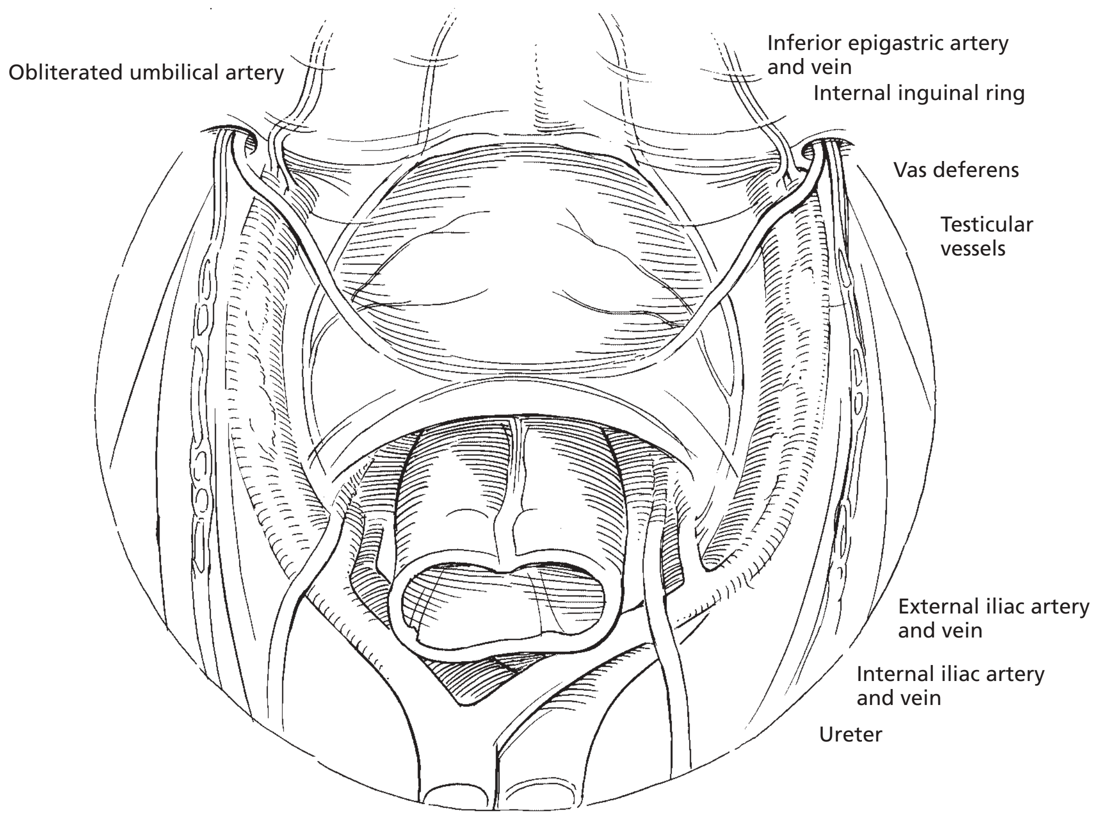

Figure 77.3 Pelvic peritoneum with the underlying structures (reproduced with permission from Brooks, JD. Anatomy of the Lower Urinary Tract and Male Genitalia. In *Campbell's Urology*, 7th ed., W.B. Saunders Company; 1997, p 98.).

ment, painful subcutaneous CO_2 emphysema, pneumothorax, and intravascular CO_2 insufflation. Unsatisfactory dissection may result in poor lymphatic tissue yield. This may be more common during a surgeon's early experience with the surgery. The inability to obtain adequate exposure of the obturator–iliac regions secondary to anatomic confounders, such as obesity, large-scale adhesions, or anomalous vascular architecture, would also oblige the surgeon to convert the procedure to open surgery.

Potential postoperative complications, including lymphedema and lymphocele formation that may require percutaneous drainage, should be understood by the patient. The possibility of hematoma formation, which, if infected, may require open evacuation and drainage, should also be discussed. As with all surgical operations requiring general anesthesia, the attendant risks of pneumonia, myocardial infarction, stroke, and death should be discussed. Other less common complications encountered following LPLND include wound infection or dehiscence, lower extremity deep vein thrombosis, and obturator nerve palsy.

In addition, alternative treatment plans that would negate the need for a lymph node dissection (e.g. watchful waiting for prostate cancer) should be discussed. Furthermore, the experience and operative outcomes obtained by the surgical team should be clarified.

Preoperative preparation

Prior to LPLND, the standard presurgical evaluations are appropriate. These include a general screen of the blood chemistry as well as a hemogram, coagulation studies, a recent chest X-ray, and an electrocardiogram. A blood typing and antibody screen are mandatory since LPLND is not without significant risk of vascular injury and voluminous hemorrhage requiring emergency transfusion. If further radical surgery is planned pending a lymph node biopsy that is negative for metastatic disease, many surgeons advise the patient to bank autologous blood in the event that transfusion becomes necessary during the procedure.

The LPLND candidate is given specific instructions regarding the appropriate preoperative routine. The healthy patient scheduled to undergo LPLND alone who has no previous abdominopelvic pathology, surgery, or radiotherapy is instructed to self-administer either an oral laxative such as magnesium citrate or an enema on the evening before surgery. Decompressing the bowel in this manner decreases the risk of enterotomy. In addition, the patient should be instructed to cease oral intake past midnight and to report for admission to the hospital early on the morning of surgery. In certain clinical situations a more intensive mechanical and antibiotic bowel preparation should be administered the evening before

Figure 77.4 Patient is secured to the table in a supine position. The steep Trendelenberg position is needed.

surgery, e.g. if more extensive surgery such as radical cystectomy with urinary diversion is planned in the event the nodes are negative on frozen section examination.

All patients are administered one dose of a broad-spectrum parenteral antibiotic (e.g. 1 g cefazolin intravenously) 1 h preoperatively. On arrival in the operating room, antiembolic pneumatically cycled compression boots are placed on the patient. For improved positioning, muscle relaxation, exposure, and analgesia, general anesthesia is considered most appropriate for LPLND.

The patient is placed in a supine position on the operating table (Figure 77.4). After adequate general anesthesia is obtained, a urethral catheter and an oro/nasogastric tube are inserted.

Both the patient's arms are carefully padded and secured at their sides. Wide adhesive tape may be placed across the chest and thigh to secure the patient to the operating table. Some argue that stress to the shoulders and brachial plexus during Trendelenburg positioning may be caused by the securing of tape to this region. In the case of robotic PLND (RPLND), the patient's legs are spread apart either with Yellowfins or a specialized robotic table, which help in securing the legs. When using the Yellowfins, the legs may be lowered when the table is placed in the Trendelenburg position. Along with the padding that is fixed to the table, this holds the patient sufficiently, avoiding the use of tape in the shoulder region. The entire abdomen, including the groin and external genitals, is then antiseptically prepared and draped in a manner suitable for standard laparotomy. Access to the genitalia during surgery may be helpful in an occasional patient, especially those who are obese, since tugging on the testis can help identify the internal inguinal ring.

Instrumentation and port placement

The 10-mm, 0° or 30° laparoscope is used. The video monitoring equipment should be placed in such a manner as to allow a comfortable and unobstructed view by all members of the surgical team. Ideally, dual monitors should be used on each side of the patient, off the foot end of the operating table.

Laparoscopic lymphadenectomy

For laparoscopic PLND, four to five ports can be used (Figure 77.5). Access is achieved at the umbilicus, where a 12-mm port is placed for the laparoscope. A 5-mm port is placed on either side, approximately 8 cm lateral to the umbilical port and 2 cm inferior. If a very proximal dissection is expected, these trocars can be translated a few centimeters cephalad. In a diamond configuration, the fourth port, a 12-mm port, is placed midway between the umbilicus and the pubic symphysis in the midline (Figure 77.5A). An additional 5-mm trocar can be placed superolaterally to the right-sided trocar for additional retraction in the obese patient (Figure 77.5B). The additional trocar is also typically necessary if a laparoscopic prostatectomy or cystectomy is planned.

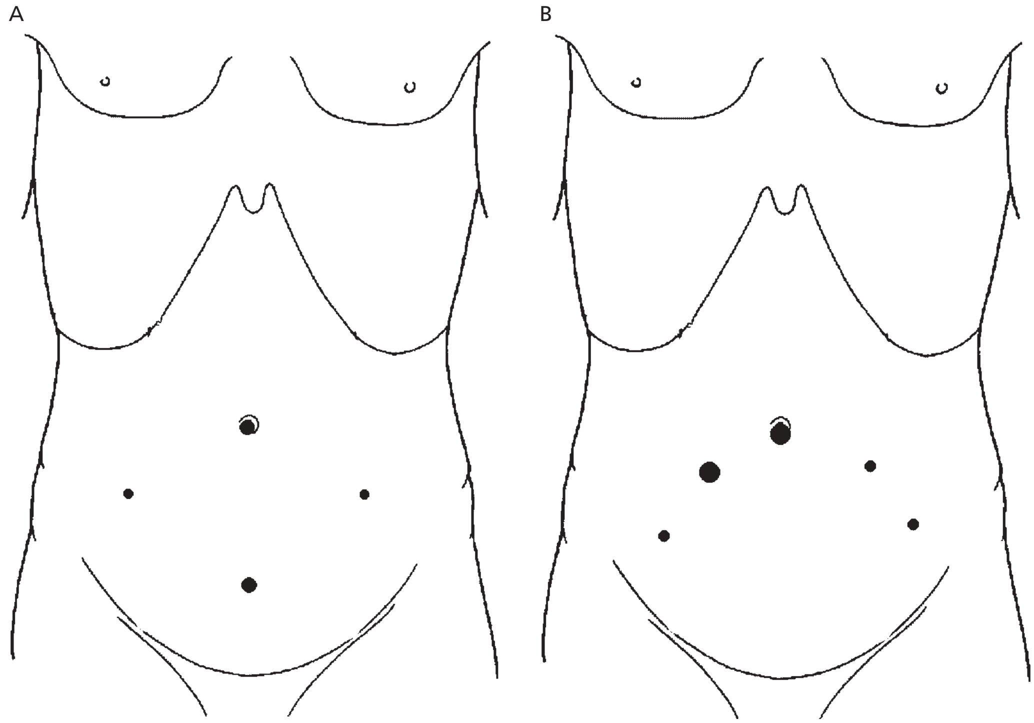

Figure 77.5 Port placement for laparoscopic pelvic lymphadectomy. (A) Diamond configuration and (B) fan configuration: more versatile if planning prostatectomy/cystectomy, and is helpful in obese patients.

Instruments that we use extensively include the Harmonic scalpel® with the curved shears (Ethicon Endo-surgery, Cincinnati, OH, USA), laparoscopic dissectors, and the suction irrigator. Bipolar forceps are invaluable to assist with hemostasis. A 5-mm three-prong or fan-shaped retractor aids in holding loops of bowel cephalad. Five- or 10-mm laparoscopic vein retractors or "mini-curved" retractors are helpful in retracting the iliac vessels laterally to facilitate improved access to the pelvic side wall and obturator fossa. Additionally, 10-mm spoon-shaped laparoscopic forceps can be used to remove smaller portions of the lymph node packet. The 10-mm specimen bag (EndoPouch®, Ethicon Endo-surgery) is used when the specimen is large or the lymph node capsule violated, and with extended LPLND.

As a precaution, particularly during the surgeon's early experience, the surgical nursing staff should have a standard laparotomy tray set-up in the operating room should the need for emergency laparotomy arise. As experience with laparoscopic surgical technique is gained, the need to convert to an open procedure will decrease; however, the open set should always be in the room ready to be used if required.

Robotic lymphadenectomy

In robotic lymphadenectomy, the patient-side cart is usually brought between the patient's legs such that the instrument trays are angled toward the pelvis. The assistant may stand on either the patient's right or left side. Similar to the laparoscopic lymphadenectomy, access is obtained at the level of the umbilicus, or slightly above the umbilicus if a very proximal dissection is expected. A 12-mm port is placed at this location, which is used as the camera port. An 8-mm robotic trocar is placed on either side of this port, approximately 7–8 cm lateral to the camera port and 2 cm inferior (Figure 77.6). These trocars can be moved superiorly if a proximal dissection is expected. An additional robotic trocar can be placed for use as an optional fourth arm, approximately 8 cm lateral to either the right or left robotic trocar. On the opposite side, but in a similar location, a 12-mm port is placed for the assistant. An additional 5-mm port can be placed 3 cm superior to the midpoint between the umbilical and right or left robotic port, on the same side as the other assistant port.

The monopolar scissors and PK dissecting forceps are typically used as the primary dissecting instruments. The Prograsp is also useful for additional retraction by the fourth robotic arm. The assistant typically uses a suction irrigator. Additionally, a prostate grasper or atraumatic grasper can be used by the assitant for additional traction. A laparoscopic spoon can be used by the assistant to remove smaller specimens. Laparoscopic clips, 5- and 10-mm Hem-o-lok® polymer locking clips (Weck Closure System, Research Triangle Park, NC, USA) may also be necessary.

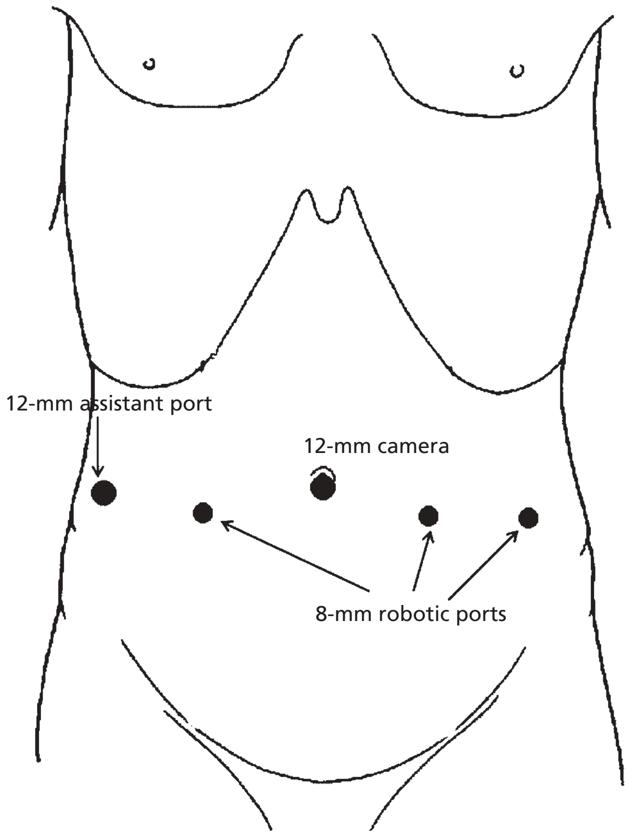

Figure 77.6 Robotic port placement. For more proximal dissection, the ports can be shifted superiorly.

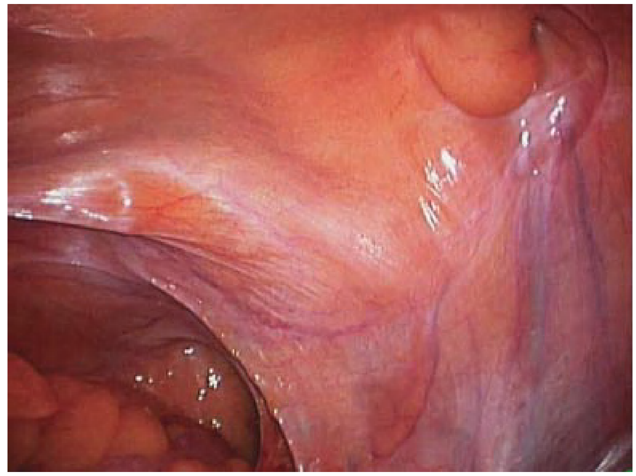

Figure 77.7 Laparoscopic view of the right hemipelvis.

Technique

Transperitoneal pelvic lymph node dissection

After adequate pneumoperitoneum has been obtained and the placement of a 10/12-mm subumbilical port has been accomplished, a 0° (or 30°) telescope is then introduced into the abdominal cavity and a thorough and systematic survey of the abdominal contents is performed to rule out injury or gross metastatic disease. Any extensive adhesions or fatty tissue deposits in the vicinity of the umbilical ligaments are noted since these findings may indicate the need for a modification of the standard diamond configuration of working port placement. Adhesions near the sites selected for working port positions may require lysis before port placement can be completed. Ports are then placed under vision in the configuration described previously.

At this point adhesions interfering with proper exposure of the obturator fossa may require lysis. This is particularly true of dissection on the left side since sigmoid colonic diverticular inflammation may create adhesions of the sigmoid colon to the pelvic side wall. Incising along the white line of Toldt should easily mobilize the sigmoid colon to allow a clear view of the obturator–iliac region. Additional reflection of the bowel cephalad allows exposure of the more proximal vessels.

It is necessary to accurately identify several important landmarks before beginning dissection of the pelvic lymph nodes (Figures 77.3 and 77.7). The testicular vessels and vas deferens should be identified as they enter the pelvis via the deep inguinal ring. The testicular vessels continue cephalad, while the vas deferens runs posteromedially over the iliac vessels and the obliterated umbilical artery (ligament) en route to its position alongside the seminal vesicles deep within the pelvis. The umbilical ligament should be seen extending from the anterior abdominal wall on its way to join the internal iliac artery near the bifurcation of the common iliac artery. It should be noted that the "obliterated" umbilical artery is often widely patent near its junction with the internal iliac artery, and has been the source of significant hemorrhage following accidental transection. In nonobese patients, pulsation of the external iliac artery may indicate its position beneath the peritoneum.

Obturator pelvic lymph node dissection

Obturator lymphadenectomy has been thought to be an appropriate procedure for the pathologic staging of patients with lower risk prostate cancer. Though recently it has been demonstrated that survival is not affected by lymph node dissection in these patients, there may be some prognostic value in patients with a risk of positive lymph nodes of less than 10%. Dissection should begin on the side that is more likely to harbor nodal metastases. This includes the side of the positive prostate biopsies or prostate nodule. If there is no preference for the side based on preoperative data, dissection of the right side is performed first since adhesions requiring colonic mobolization are more common on the left side. The initial incision through the posterior peritoneal

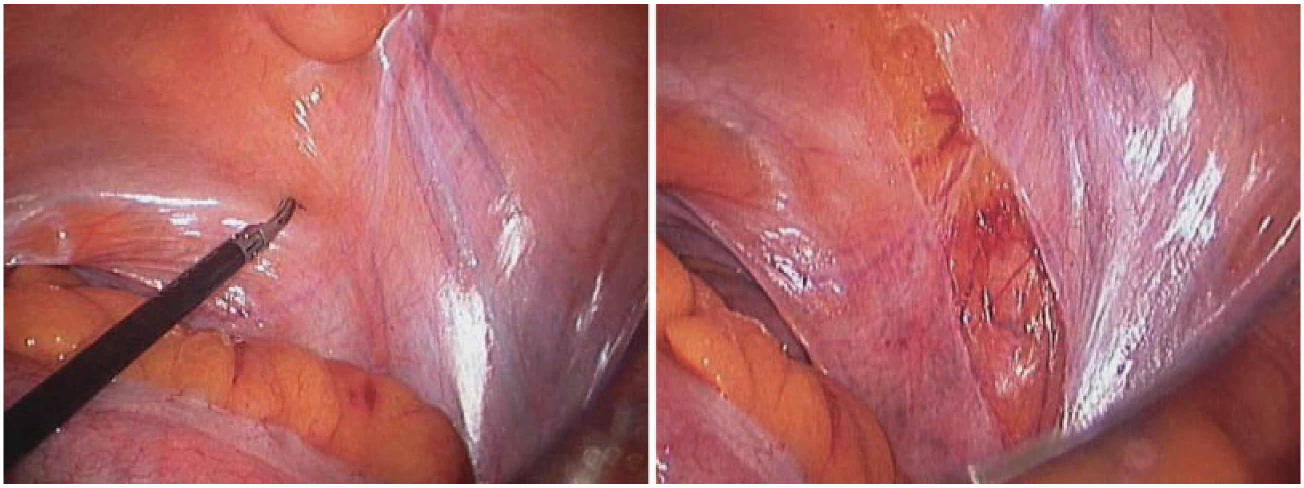

Figure 77.8 Incision is made in the peritoneum just lateral to the obliterated umbilical artery.

membrane begins at a point approximately midway between the obliterated umbilical artery and the internal inguinal ring high over the pubic bone. It is then extended cephalad, medial to the external iliac artery, toward a point near the bifurcation of the common iliac artery (Figure 77.8). The anatomic relationship of the ureter to the bifurcation of the common iliac artery must be well conceptualized by the surgeon to avoid transection requiring stenting or possibly open repair. The vas deferens with its deferential artery is then identified, dissected free, and transected using electrocautery. Alternatively, an incision can be made just lateral to the medial umbilical ligament. The bladder is reflected with blunt and sharp dissection away from the sidewall. The peritoneum is then carefully incised proximal to the vas deferens, along the direction of the external iliac artery. This creates exposure for the whole extent of the dissection. When using the robot, the fourth arm or assistant can help retract the bladder medial to maintain exposure.

The external iliac vein is exposed by careful dissection of all fibrofatty lymph node-bearing tissue medial to the external iliac artery. With the use of blunt and sharp dissection techniques, the lateral border of dissection is formed by clearing all fibrolymphatic tissue from the anterior and medial surfaces of the external iliac vein, as well as the tissue underneath the vein, extending to the side wall.

Gentle medial traction placed on the obliterated umbilical artery forms a plane delineating the medial boundary of the obturator node packet. Blunt dissection lateral to the obliterated umbilical artery is continued inferiorly to develop this plane to the level of the pubic bone and Cooper's ligament (Figure 77.9). This completes the inferior apex of the dissection. In this area venous variations are frequently encountered. Not uncommonly an accessory obturator vein may be identified as it joins the external iliac vein just after the iliac vessels enter the pelvis through the femoral canal. With careful manipulation, the inferior apex of the obturator lymph node packet may be maneuvered beneath this tributary, but as is often the case, clips should be placed on the accessory vein proximally and distally, followed by division, before the distal lymph node packet can be freed. Five- or 10-mm Hem-o-lok® clips are recommended since these locking clips are less prone to dislodge during further dissection in the region. Alternatively, bipolar cautery or PK forceps can sufficiently cauterize these vessels in most cases.

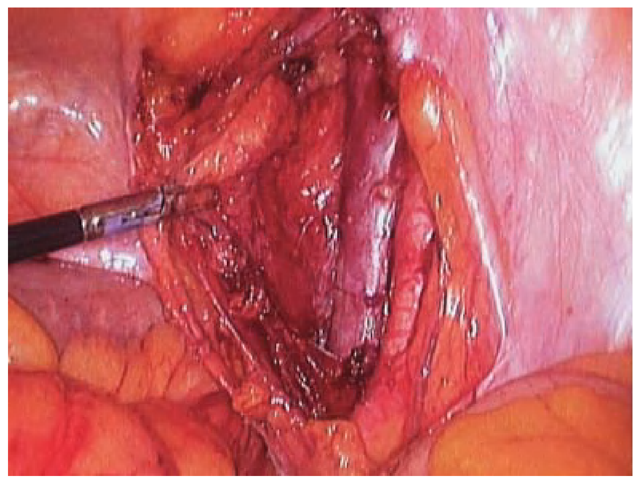

Figure 77.9 Dissection is carried out distally to the pubic bone along the external illac vessels.

The distal extent of the lymph node packet is freed with judicious use of electrocautery or ultrasonic shears. A clip is used at the distal end to occlude lymphatics and minimize the risk of a postoperative lymphocele.

The free distal apex of the node packet is then grasped and elevated using proximally directed traction. With blunt dissection at the base of the node packet, the underlying obturator nerve and vessels should come into view as gentle traction draws the packet superiorly. During dissection of the lymph node packet toward the bifurcation of the common iliac artery, any small blood or lymphatic vessels encountered should be sealed with electrocautery or ultrasonic shears. Normally the obturator vessels are preserved as their course is medial and slightly posterior to the obturator nerve. These vessels may be controlled and divided if required. Again, it must be remembered that as the dissection nears the bifurcation of the common iliac artery, the proximity of the ureter puts it at risk of unintentional injury.

When the level of the common iliac bifurcation is reached, the proximal lymphatic vessels are cauterized, clamped with a Hem-o-lok clip, and divided, resulting in a free lymph node packet (Figure 77.10). With 10-mm spoon-shaped laparoscopic forceps, the free lymph node packet is delivered through a 10/12-mm port using a gentle twisting motion. The flap valve at the entrance to the port must be manually opened during extraction of the lymph node packet to avoid shearing and loss of lymphatic tissue within the barrel of the sheath. Laparoscopic visualization of the intracorporeal open end of the sheath during extraction of the lymph node packet will further ensure that no lymphatic tissue is dislodged from the packet during removal, and facilitate immediate location and recovery of any lymphatic tissue accidentally sheared from the packet during extraction. If the lymphatic tissue is large or there is concern of violation of the lymph node capsule, a 10-mm entrapment sac (EndoPouch®) may be used for specimen retrieval.

If immediate radical surgery is planned pending a negative histopathologic evaluation of the lymphatic tissue specimen, the lymph node packet is sent for immediate frozen section analysis and attention is then turned to the opposite side. If radical surgery is not planned, we rarely order frozen-section histopathologic evaluation of the lymph node specimens. If immediate radical surgery is not planned, we send the nodes from the first side for frozen-section analysis, since a positive node on the first side could obviate dissection on the contralateral side. The false-negative rate of frozen section evaluation of lymph node sampling can be as high as 19% [82]. The table is rotated in the opposite

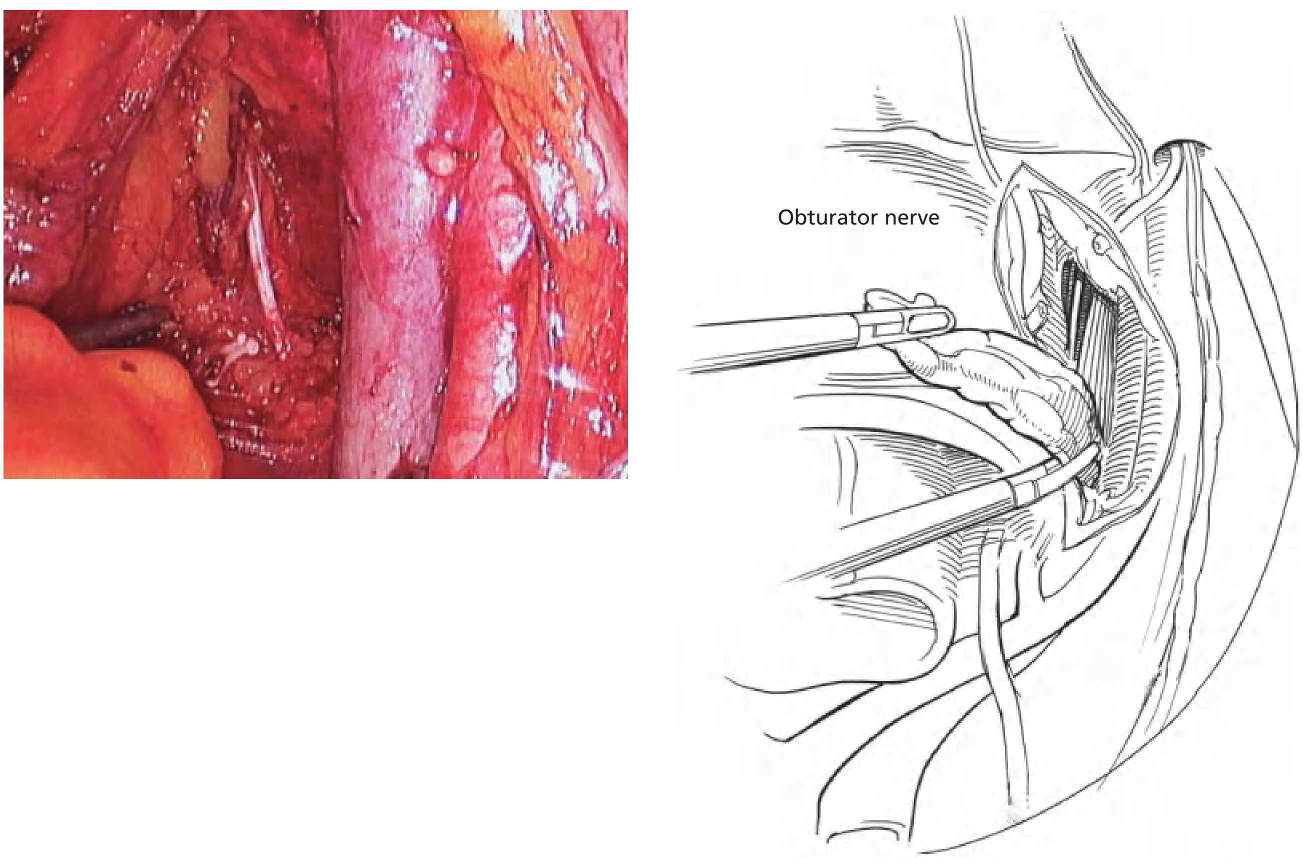

Figure 77.10 Tissue is removed from the medial aspect of the external iliac vessels, pelvic side wall, and the obturator nerve up to the iliac bifurcation.

direction and a similar dissection proceeds on the contralateral side.

At the conclusion of the laparoscopic procedure, a thorough evaluation of the abdomen is necessary. Particular attention is directed to the operative sites to ensure that meticulous hemostasis has been achieved. Intra-abdominal pressure is lowered to approximately 5 mmHg to permit identification of any venous bleeding formerly tamponaded during the higher intra-abdominal pressures maintained throughout the procedure. Since the physical presence of the ports may tamponade any potential bleeding from a lacerated abdominal wall vessel, the secondary ports are all removed under direct laparoscopic visualization. The primary port is removed over the laparoscope, the laparoscope being the last instrument to exit the intra-abdominal space. This guards against herniation of abdominal contents and allows for a final inspection for hemorrhage formerly tamponaded by the camera port. In addition, digital exploration of all 10/12-mm port incisions may be performed to rule out herniation before closure. Any residual CO_2 is expressed out of the abdominal cavity and all puncture sites that are 10 mm or larger are closed separately with a single 2-0 polydioxanone suture on the fascia. The oro/nasogastric tube is removed before the patient emerges from the anesthesia. The patient is then transferred to the postanesthesia care unit for routine postoperative monitoring.

Nuances with robotic lymphadenectomy

With the increased use of robot-assisted surgery for prostate and bladder surgery, pelvic lymphadenectomy is often performed robotically. The manner of dissection is the same for robotic surgery, but a couple of differences warrant description. As mentioned previously, due to the decreased instrument range, careful placement of the ports is necessary. If a proximal dissection is expected, the ports should be placed more cephalad than usual. Camera angle can also improve the range that can be visualized via the robotic camera. Distally, a 0° or 30° upward camera may be helpful, but more proximally, a 30° downward camera is helpful.

A fourth robotic arm can aid in retraction of the bladder medially on the side opposite to which it is placed. For dissection on the same side as the fourth arm, the assistant retracts the bladder medially. The fourth arm can then be used to hold the lymph node packet on traction.

Rotation of the table in laparoscopic lymphadenectomy helps retract the bowel away from the proximal areas of dissection. However, this is not possible in robotic lymphadenectomy. Thus, mobilization of the bowel medially by reflecting it off the posterior peritoneum is important to provide access. Additional retraction with a fan via the assistant port may be necessary.

Extended pelvic lymph node dissection

As previously mentioned, certain clinical indications merit a more extensive lymph node dissection:

- Carcinoma of the urinary bladder, urethra, or penis;
- Carcinoma of the prostate in the absence of gross obturator lymph node positivity in (1) PSA elevation in excess of 20 ng/mL (Hybritech assay); (2) a Gleason score of 8 or greater (as lymph node positivity would be expected in over 40% of cases); and (3) clinical stage C (T3) disease.

In order to gain access to this broader region of dissection, a more extensive mobilization of the sigmoid colon and cecoappendiceal regions are required. Alternatively, an inverted V peritoneotomy has been described that may provide greater exposure of the obturator–iliac region [41]. This includes a second peritoneal incision that originates at the same point over the pubic bone as the initial incision, and continues posteromedially and equidistant to the initial incision. This forms a triangular peritoneal free flap based along the medial umbilical ligament and the spermatic cord, which, when elevated, allows a more thorough exposure of the underlying obturator–iliac region. Full access to the lymphatic tissue deep to these vessels is facilitated by gentle medial retraction of the external iliac artery and vein.

Boundaries of pelvic lymphadenectomy (Table 77.1)

Lateral border

In contrast to limited PLND, the lateral border of extended PLND includes the lymph nodes anterior and lateral to the external iliac vein to the level of the genitofemoral nerve. The incision of the peritoneum is made lateral to the medial umbilical ligmament, and the obturator lymph nodes can be dissected as before. The lymph nodes covering the external artery are then rolled over the artery. The genitofemoral nerve is identified, and the peritoneum and lymphatic tissue is divided just medial to this. This can be extended cephalad to dissect the tissue between the psoas and the lateral aspect of the common iliac artery. Gentle retraction of the artery medially can aid in this dissection.

Proximal limit

The proximal limit of the extended PLND for prostate cancer is the common iliac artery, while for bladder cancer it should include the aortic bifurcation. Some

Table 77.1 Boundaries of pelvic lymphadenectomy.

Boundaries	Limited	Extended – prostate	Extended – bladder
Lateral	External iliac vein	Genitofemoral nerve	Genitofemoral nerve
Medial	Medial umbilical ligament	Ureter, bladder	Presacral nodes
Inferior	Pubis	Pubis	Pubis
Superior	Bifurcation of common iliac artery	Distal common iliac artery	Aortic bifurcation
Posterior	Obturator nerve	Presciatic tissue, hypogastric artery	Presciatic tissue, hypogastric artery

sources include the distal aortic nodes up to the level of the inferior mesenteric artery. In order to reach these lymph nodes, it must be ensured that the ports are placed high enough on the abdomen to reach this location, which may require the camera port to be placed cephalad to the umbilicus. Mobilization of the cecum and sigmoid colon aid in obtaining adequate exposure of this region. The dissection usually starts on the right side, as the exposure and dissection are more difficult on the left due to the presence of the sigmoid colon. Incision of the peritoneum following the direction of the common iliac artery allows safe exposure of this area. It is helpful to divide the lymph node packet overlying the common iliac artery, taking care to avoid the ureter. The lymph node tissue is rolled off the lateral surface of the external iliac artery. The remaining packet is retracted medially to visualize the common iliac vein. Additional dissection proceeds medial to cover the presacral lymph nodes. This is more easily approached from the right, as the sigmoid can be retracted laterally to provide exposure. Excessive deep dissection in this area should be avoided to prevent bleeding. The aortic nodes can be dissected with this exposure also. The left-sided dissection is performed in a similar manner.

Posterior dissection

The lymph node tissue that lies underneath the obturator nerve represents a significant drainage region for both prostate and bladder cancer. It encompasses the lymph nodes along the medial surface of the internal iliac artery. These lymph nodes can be accessed after the dissection of the obturator lymph nodes. The obturator lymph nodes, when freed, except at the base, can be passed underneath the obturator and retracted medially to provide exposure. Alternatively, the obturator nodes can be removed as a separate packet. Vessel and lymphatic branches are found laterally and posteriorly and should be clipped as the packet is retracted medially (Figure 77.11).

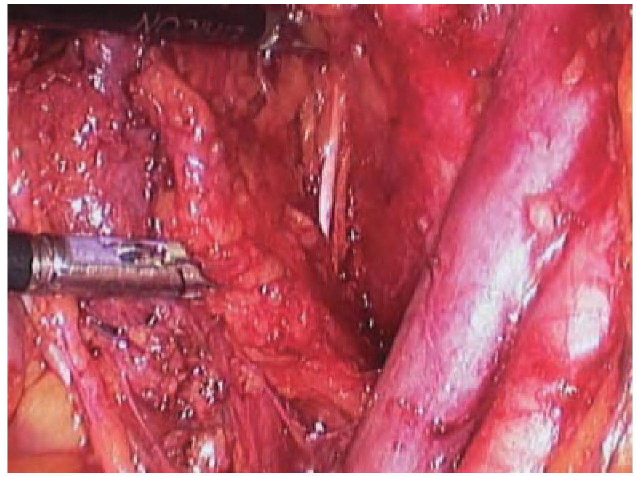

Figure 77.11 Nodal tissue is removed beneath the obturator 1nerve, medial to the internal iliac vessels. Tissue medial to this can also be removed.

Extraperitoneal pelvic lymph node dissection

It is evident that by maintaining the integrity of the peritoneal membrane, the risks of visceral injury, intraperitoneal spillage of potentially tumor-laden lymphatic tissue, and postoperative development of intra-abdominal adhesions associated with direct instrumentation and manipulation of the intraperitoneal contents may be decreased or avoided. Additionally, tedious and time-consuming adhesiolysis, followed by mobilization of sigmoid colonic and cecoappendiceal regions that often must precede exposure of the obturator–iliac regions, is avoided with the extraperitoneal approach. Furthermore, the intact peritoneum may help ameliorate the difficulty of obtaining adequate exposure commonly encountered in the obese patient. By retaining the fat-laden loops of bowel and omentum (that tend to fall into the operative field) within the peritoneal cavity, the intact peritoneum passively facilitates exposure of the obturator–iliac region. This in turn may lessen the need for the extreme Trendelenburg position typically used to gravitate these barriers away from the operative site.

On the contrary, several disadvantages of this alternative approach have been noted. The working space available for extraperitoneal LPLND is limited by the ability to successfully develop and insufflate the properitoneal space. Even with excellent expansion and CO_2 insufflation, the properitoneal working area is much more confined than in the intraperitoneal space. Also,

the balloon dissection required to develop the properitoneal space produces a shearing effect between the parietal surface of the peritoneal membrane and the overlying fascial layer. This results in a tattered appearance of the properitoneal space. This effect, combined with the cephalad displacement of the vas deferens, may present a confusing picture to the laparoscopic surgeon. The lymph nodes along the internal iliac artery, as well as more proximally placed lymph nodes, are difficult to reach with this technique [83].

In a patient with a history of lower abdominal or pelvic intra- or extra-peritoneal surgery, the resultant postoperative sequelae of fibrosis and scarring within the tissue planes of the abdominal wall may severely limit expansion of the properitoneal space. Similarly, the fibrosis and scarring following extraperitoneal LPLND may complicate future regional procedures such as radical retropubic prostatectomy. In addition, the potentially higher likelihood of lymphocele formation and extensive subcutaneous CO_2 emphysema may complicate the extraperitoneal LPLND candidate's postoperative course.

Creation of the extraperitoneal space

The patient is placed supine under general anesthesia with endotracheal intubation. About 2 cm below the umbilicus, a 3-cm vertical midline incision is carried inferiorly and deepened to the level of the rectus abdominis fascia. The properitoneal space is then entered by splitting the rectus abdominis and transversalis fascia. The latter fascial layer is deep to the rectus abdominis muscle below the umbilicus and arcuate line. A properitoneal space is developed using blunt finger dissection to the extent that a balloon dilation device can be introduced.

A modification of the device described by Gaur *et al*. for creation of the retroperitoneal working space while attempting the first extraperitoneal laparoscopic nephrectomy has proved successful in expanding the properitoneal space [84]. This device features the finger cot of a transurethral resection drape secured to a 20F red rubber (Robinson) catheter by silk-free ties. The thicker polyethylene natural rubber material has demonstrated the ability to withstand pressure exerted by injection of the 800–1000 mL of saline solution required to adequately expand the properitoneal space. This is important since balloon rupture during expansion will mandate a thorough search of the properitoneal space for fragments. Fortunately, if the polyethylene balloon ruptures, the fragments tend to be large and easily recoverable. Latex fractures into smaller pieces, which may lead to a serious inflammatory or allergic response if retained. A commercially available preperitoneal balloon may be used to create the extraperitoneal working space.

With successful dilation of the space of Retzius, the pubic bone and external iliac vessels become visible. We use a self-retaining, 10-mm Bluntport trocar which has a inflatable balloon and a foamgrip anchoring device (US Surgical, Norwalk, CT, USA). Twelve to 15 mmHg of CO_2 is insufflated through the cannula. In the standard diamond configuration the working ports are then placed carefully into the properitoneal space so as to avoid traversing the peritoneal membrane. The working ports are placed under direct laparoscopic guidance. Should the peritoneal membrane be violated, the properitoneal space will likely be obliterated. This situation will necessitate conversion of the port placement from the extra- to an intra-peritoneal position.

Afferent lymphatics are controlled with clips or bipolar cautery to minimize the possibility of a postoperative lymphocele. With the exception of creating a peritoneotomy, extraperitoneal LPLND proceeds in the same sequence as described for the intraperitoneal approach to obturator lymph node dissection once the ports are in place.

Postoperative care

All patients are admitted to hospital following laparoscopic surgery. They receive two additional postoperative doses of a parenteral broad-spectrum antibiotic at an 8-h interval and their diet is advanced as tolerated. Ambulation should be tolerated on the evening of surgery, and any postoperative pain should be manageable with oral analgesics; parenteral narcotics are rarely indicated. Most patients are discharged from hospital within 24 h of surgery and should be able to resume normal activity within 1 week.

Results

The results of several series of patients who underwent LPLND are summarized in Table 77.2. The transperitoneal approach is most widely used. Compared to the extraperitoneal approach, there is more operating space and the anatomic landmarks are easier to identify with the transperitoneal approach. LPLND retrieves a number of nodes that is similar to that with the open approach, in experienced hands. Compared to open surgery there is a shorter convalescence and hospital stay [85, 86].

There are few reported series of patients who undergo the extraperitoneal approach. In a series of 36 patients from Das in 1996, the operative time was between 50 and 110 min, with a blood loss of 30–65 mL [86]. In three patients the procedure was not possible via the laparoscopic approach. The mean number of nodes harvested was 12.2, and in 16.6% of patients metastatic prostate cancer was detected on frozen-section analysis.

Table 77.2 Results of transperitoneal laparoscopic pelvic lymph node dissection (LPLND) in the English literature.

*Both transperitoneal and extraperitoneal approaches were used.
LRP, laparoscopic radical prostatectomy.

Postoperative complications included a hematoma in one patient and a lymphocele in another [86].

The theoretical benefits include less risk of bowel injury, decreased incidence of postoperative ileus, and a shorter operative time. Twenty-two patients were randomized to transperitoneal or extraperitoneal approaches. The duration of surgery was less with the extraperitoneal group (87 vs 117 min). However, four patients in the extraperitoneal group were converted to the open approach due to epigastric artery bleeding and problems with gas leakage. Lymphoceles developed in two patients in the extraperitoneal group [87].

In a comparative study between similar groups of 12 and six patients who underwent transperitoneal LPLND and extraperitoneal LPLND, respectively, it was determined that the absorption of CO_2 was significantly greater and more rapid during extraperitoneal LPLND. However, in all but one patient hypercarbia and acidemia were prevented by an increased ventilatory rate. The extraperitoneal approach may not be the preferred option in patients with cardiopulmonary disease [88]. The operative time should be minimized and subcutaneous emphysema avoided to decrease the incidence of hypercarbia.

The effectiveness of LPLND has been documented with similar nodal yields when compared to open PLND [89–91]. Rukstalis *et al.* performed open surgery immediately following LPLND to determine the completeness of the laparoscopic approach. They found that 87–95% of the nodes could be removed laparoscopically [92]. The effect of inadequate nodal excision during the learning curve was demonstrated by Guazzoni *et al.* in 1994 [93]. Open surgical revision of the lymphatic tissue during radical retropubic prostatectomy in 30 patients who underwent LPLND, revealed a mean of over six residual lymph nodes in each patient. The number of residual nodes progressively decreased, especially after the first 20 patients.

Complications

Complication rates reported for LPLND and RPLND range from 3.7% to 33%, with most complications being minor [68, 94–96]. The complication rate decreased markedly with the surgeon's experience with the operation. In a study by Lang *et al.* the complication rate was 14% in the first 15 cases and only 4% in the next 50 cases [97]. In recent years, increasing numbers of residents are being trained in advanced urologic laparoscopy during their residencies. Furthermore, many more advanced laparoscopic procedures like nephrectomies and prostatectomies are being performed. The learning curve for this operation is likely to be much less.

The complications reported following LPLND are listed in Table 77.3 [98]. Lymphoceles are infrequently reported following LPLND. However, subclinical lymphoceles were detected in 30.4% (seven) of patients who underwent pelvic CTs following LPLND prior to undergoing radiotherapy [91]. Only 3.5% (two) of patients developed symptomatic lymphoceles. One of these patients required percutaneous drainage with sclerotherapy; the lymphocele resolved spontaneously in the other patient [99]. Symptomatic lymphoceles are more frequently seen following extraperitoneal LPLND, since the peritoneal drainage of the lymphatic fluid is not available. Prophylaxis against deep vein thrombosis requires the use of an intermittent pneumatic compression device during and after surgery. Subcutaneous heparin or enoxaparin (Lovenox®) can also be given, and is becoming standard at many institutions. Though there has been previous concern about increased blood loss or lymphoceles with such pharmacologic prophylaxis, there is evidence to suggest that there is no, or at most a very small, difference in blood loss or lymphoceles with prophylaxis. In a prospective series of 579 patients, the use of subcutanseous heparin did not influence the rate of blood loss or lymphoceles [100]. Koch *et al.* found a slight increase in the incidence of postoperative wound hematomas and lymphoceles

Table 77.3 Complications of transperitoneal laparoscopic pelvic lymph node dissection (adapted from Gill and Clayman [98], with permission).

Total number of patients (multiple centers)	442
Total number of complications	59 (13%)
Intraoperative complications (n = 19):	
Anesthetic complications	1
Unable to access peritoneum	1
Organ injuries:	
Vascular	9
Bladder	3

Retroperitoneal abscess	1
Secondary open surgical intervention	13
Complete lymphadenectomy could not be done	17

with the use of low molecular weight heparin in 160 patients undergoing open prostatectomy, but concluded that its use was generally safe [101]. The incidence of scrotal and penile edema and leg edema was 28% and 10%, respectively, in patients undergoing extended pelvic lymphadenectomy [102].

Vascular injuries specific to PLND can occur during dissection of the nodal tissue in the vicinity of the external iliac vein and aberrant obturator vessels. The external iliac vein may be compressed by the intra-abdominal pressure and therefore may not be readily apparent. The intra-abdominal pressure can be reduced to 10 or 5 mmHg for better visualization of the vein. The pulsation of the external iliac artery is a landmark that can help with localization of the vein that lies medial to the artery. Should vascular injury occur, increasing the intra-abdominal pressure to 20 mmHg and direct compression on the bleeding surface should be the initial maneuver. Hemostatic adjuncts, such as gelatin matrix (e.g. Floseal®; Baxter, Deerfield, IL, USA) and oxidized methylcellulose (e.g. Surgicel®; Johnson & Johnson, New Brunswick, NJ, USA) when combined with compression are most helpful in this situation. In rare situations, proximal and distal control is obtained and suturing is performed. However, the vessels, especially veins, are friable in this region, making it possible to worsen the vascular injury by suturing. Thus, laparoscopic suturing of these injuries should only be attempted if the surgeon is experienced with intracorporeal suturing. Bipolar coagulation should also be avoided if the injury is directly on the larger vessels as this will usually worsen the injury. If bleeding continues, other measures, including conversion to open surgery or endovascular stenting, may be required.

Injury to the bladder may occur during extended LPNLD where the medial boundary can extend to the bladder. The bladder can be repaired in two layers with intracorporeal suturing using 2/0 polyglactin suture. Ureteral injury should be avoided at the bifurcation of the external iliac artery, by identification of the ureter. During more caudal dissection the ureter should not be encountered if the dissection remains lateral to the medial umbilical ligament. Ureteral injury can be repaired laparoscopically if the injury is immediately identified and if the distal segment is healthy and viable. If there is any doubt of the viability of the distal ureter, ureteral reimplantation is recommended by either a laparoscopic or open approach, in which a refluxing, extravesical anastomosis is adequate

Port site metastases

Port site metastases have been reported to our knowledge in three cases of LPLND for urologic malignancies: one for prostate cancer and two for bladder cancer [103–105]. An entrapment sac was not used in all these cases. Both the bladder TCCs were T3 lesions. It is therefore advisable that when LPLND is being performed for TCC or advanced high-grade prostate cancer, an entrapment sac be used to minimize contamination of the port site during specimen retrieval. The risk of port-site metastases is however exceedingly small. When the risk for recurrence is high, other precautions that have been recommended include avoidance of nodal capsular rupture, trocar fixation to prevent dislodgment, avoiding gas leakage along and around the trocar, placing drainage when needed before desufflation, povidone–iodine irrigation of instruments, trocars, and port-site wounds, and suturing 10-mm and larger trocar wounds [106].

Mini-laparotomy

Surgeons without laparoscopic skills can perform the PLND via a small midline 6-cm incision. Bilateral inguinal incisions with aggressive retraction have also been successful. Perrotti *et al.* compared the mini-laparotomy with LPLND and standard open surgery and found that nodal yield with mini-laparotomy was similar to standard surgery and morbidity, and hospital stay was similar to LPLND. The operative time was 90 min with the mini-laparotomy compared to 190 min for LPLND [107]. Herrell *et al.* in a similar study noted no difference in number of nodes obtained by either of these approaches. Multiple complications occurred in the standard open group with no complications in the other two groups [108].

Conclusions

LPLND dissection for prostate cancer is being performed in selected patients, since most patients with prostate cancer in developed countries have early, localized malignancy. However, recent data suggest a benefit in performing an extended lymphadenectomy for those patients with high-risk prostate cancer and for any bladder, urethral or penile cancer. A meticulous dissection that duplicates open surgery is required when this operation is performed. Lymph node dissection as part of laparoscopic radical prostatectomy and laparoscopic cystectomy will be performed in increasing numbers in the next decade.

CHAPTER 78

Endoscopic Subcutaneous Modified Inguinal Lymph Node Dissection for Squamous Cell Carcinoma of the Penis

Jay T. Bishoff

Intermountain Urological Institute, University of Utah College of Medicine, Salt Lake City, Utah, USA

Introduction

The extent of metastatic disease to the lymph nodes is the most important prognostic indicator of survival in patients with squamous cell carcinoma of the penis. Almost 50% of penile cancer patients will harbor metastatic nodal disease. Lymphadenectomy is frequently required for adequate cancer staging and can also be curative when cancer is isolated to the penis and regional nodes [1, 2]. However, inguinal lymph node dissection is not without potential morbidity. Serious, life-altering complications have been associated with inguinal lymph node dissection, including infection, flap necrosis, vascular erosion, and lower extremity lymph edema, and for this reason controversy still surrounds the utility of bilateral and prophylactic dissection.

In 2002, Ian M. Thompson conceived the idea of applying laparoscopic techniques in an endoscopic, subcutaneous approach, with the hope of decreasing the morbidity associated with open surgery by preserving the continuity of the lymphatic and vascular supply to the overlying skin. Working together, we combined different techniques from traditional laparoscopy, subcutaneous endoscopic brow lift, and subcutaneous saphenous vein harvest to formulate an approach using laparoscopic instruments for inguinal node dissection in staging penile cancer. The result is the endoscopic subcutaneous modified inguinal lymphadenectomy (ESMIL) procedure, which mimics the same oncologic approach, anatomic boundaries, and extent of dissection traditionally performed through an open incision.

We first explored the feasibility of this new procedure in several fresh cadaver studies, and in 2003 a patient with T3 N1 MO squamous cell carcinoma of the penis underwent the first ESMIL procedure [3]. Since our initial report, several teams around the world have reported on the utility of this procedure in the treatment and staging of penile, melanoma, and gynecologic cancers. In one series, the investigators performed ESMIL on one leg and a traditional open procedure on the opposite leg in 10 patients undergoing bilateral procedures, and ESMIL alone in five patients. They found no difference between the groups in the number of nodes removed: 10.8 in the ESMIL group and 9.7 in the open group. Complications were seen in 70% of the open cases and in only 20% of the endoscopic group. In the open cohort, skin-related complications were seen in five limbs and lymph complications in two patients. In the endoscopic patient group, skin-related complications were seen in one patient, hematoma in one patient, and lymphorrhea in one patient for 12 days with the drain in place. After the endoscopic dissection, all patients were discharged within 24 h. In the open group the average hospital stay was 6.4 days. At a mean follow-up of 31 months, there were no local or trocar site recurrences [4].

In a second series, 25 ESMIL procedures were performed in 16 patients for scrotal, penile, urethral or melanoma cancer. Both the superficial and deep nodes were removed in these patients; the average number of nodes removed was nine. Complications occurred in two patients, cellulitis in one and a seroma in

Smith's Textbook of Endourology, Third Edition. Edited by Arthur D. Smith, Gopal H. Badlani, Glenn M. Preminger, Louis R. Kavoussi.

the other. No patient suffered lymph edema or flap necrosis [5].

Indications/contraindications

ESMIL is indicated when traditional inguinal lymphadenectomy would be required for staging squamous cell carcinoma of the penis. Patients with nonpalpable nodes or small (<1 cm) mobile nodes at high risk for inguinal node involvement are considered good candidates for endoscopic node dissection. Approximately 10% of patients with pTa and pT1 grade I penile tumors will have positive nodes when inguinal nodes are not enlarged. Fifty percent of patients with pT2 tumors and grade III tumors will demonstrate positive inguinal lymph nodes.

Both stage and grade are predictive of nodal involvement. Verrucous carcinoma and carcinoma *in situ* are both associated with a low risk for nodal metastasis. However, 70% of stage T2 cancers have positive nodes. Grade I tumors have a 30% chance of spread to lymph nodes, while approximately 85% of patient with grade III tumors have inguinal node involvement [2]. Because cross drainage from the affected side to the contralateral side is a well-known occurrence, bilateral dissection is indicated in patients at high risk for metastatic disease (stage T2 or greater or grade II–III tumors).

Patients with large, fixed inguinal lymph nodes have a relative contraindication to ESMIL. In these patients it can be very difficult to dissect the superior aspect of fixed, matted lymph nodes with an endoscopic technique and as a result, they may be better candidates for traditional open surgery.

Preoperative preparation and evaluation

A complete metastatic evaluation should be performed prior to biopsy of the presenting penile lesion or partial penecotomy when indicated. The presence of carcinoma of the penis is established with biopsy to determine the diagnosis, extent of invasion, presence of vascular invasion, and grade of the lesion prior to lymphadenectomy. Distant metastatic disease without lymph node involvement is rarely seen. However, distant metastatic spread to bone, brain, liver, and lung should be considered as part of the overall work-up for penile cancer. Computed tomography of the pelvis and inguinal region can be helpful in determining the presence of large pelvic and inguinal nodes, especially in the obese patient.

Waist-high elastic stockings should be fitted prior to surgery. Preoperative intravenous antibiotics for skin flora coverage are given 60 min prior to the skin incision. A sterile preparation of the area is performed in the usual fashion.

Operating room configuration and patient position

The operating room (OR) is configured so that all staff can view the procedure. The surgeon's monitor is placed on the contralateral side of the dissection, near the shoulder and arm of the patient. A second monitor is placed on the opposite side in the case of bilateral dissection or as needed for viewing by the entire team.

The patient is placed in a supine position, with the ipsilateral knee flexed and hip abducted. The foot on the side of dissection is secured to the contralateral leg for a unilateral dissection or both feet are secured together for a bilateral procedure. A pad placed under the bent knee will help maintain the correct position (Figure 78.1).

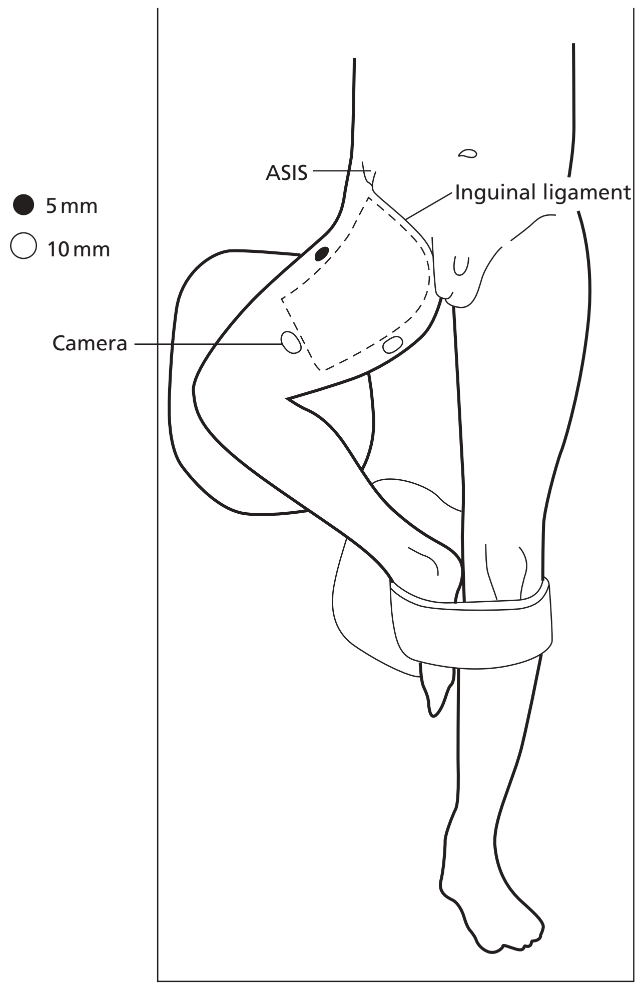

Figure 78.1 Patient is placed in a supine position, with the ipsilateral knee flexed and hip abducted (reproduced from Bishoff J.T., Kavoussi, L.R., eds. *Atlas of Laparoscopic Urologic Surgery.* Philadelphia: Saunders Elsevier, 2007, with permission).

Procedure

The key points are listed in Table 78.1.

Table 78.1 Key points in endoscopic subcutaneous modified inguinal lymph node dissection.

• Using an illuminated instrument or the light directed from the laparoscope will improve visualization of the initial dissection and establishment of the correct tissue planes during placement of the first two trocars
• Entry into the correct plane of dissection with scissors facilities dissection after trocars have been placedContinuous flow of CO_2 allows rapid clearing of water vapor or smoke during dissection in the small working space
• A working pressure of 5 mmHg is sufficient to maintain visualization while avoiding spontaneous infiltration beyond the boundaries of dissection
• The LigaSure 5-mm device offers excellent hemostasis, rapid dissection, and less need for evacuation of smoke or vapor compared to ultrasonic shears
• Key landmarks are readily identified and transillumination of the skin facilitates orientation
• Following the saphenous vein helps with identification of landmarks but as many branches as possible should be preserved to decrease lymph edema in the lower extremity
• All tissue should be divided with ultrasonic energy or electrocautery to decrease the incidence of prolonged lymphatic leak

Trocar placement

Before placing the first trocar, the limits of the dissection are marked on the skin. This important step will guide the surgeon by preserving the appropriate orientation once the skin becomes distorted from the insufflation used to create the working space. A line is drawn from the pubic tubercle to the anterior superior iliac crest. The width of the area of dissection is approximately 11–12 cm and the length 15 cm down the medial thigh and 20 cm down the lateral thigh (Figure 78.2).

Trocar placement is the same for the left and right sides. The trocars are placed just outside the delineated area of dissection. Initially, a 2.5-cm incision is made over the saphenous vein, 15 cm below the pubic tubercle. The incision is continued down to expose adipose tissue. It is important to avoid making the incision any larger than 2.5 cm to prevent CO_2 escape during the procedure, once the trocar is inserted and the subcutaneous cavity insufflated. A second 2.5-cm incision is made

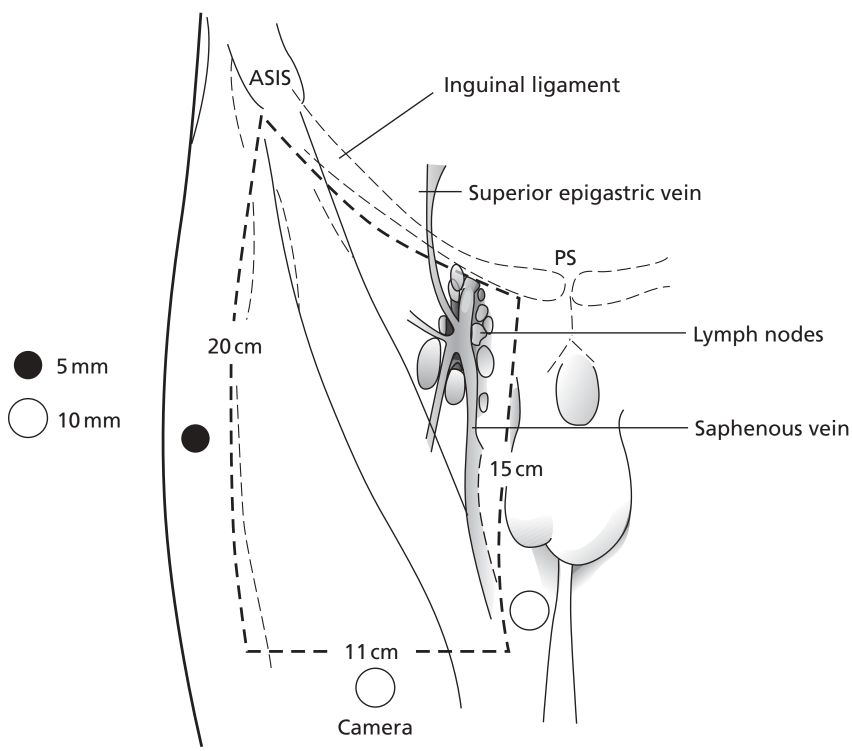

Figure 78.2 Limits of dissection are drawn on the skin (reproduced from Bishoff J.T., Kavoussi, L.R., eds. *Atlas of Laparoscopic Urologic Surgery.* Philadelphia: Saunders Elsevier, 2007, with permission).

in the center of the inferior boundary of dissection (Figure 78.2).

Before the two 10-mm blunt tipped trocars (Covidien, Autosuture, Mansfield, MA, USA) are placed, the surgeon uses these two incisions to establish the correct plane of dissection, working from one toward the other. Time spent doing this at the start of the procedure will significantly shorten the overall length of the procedure. Sharp, fine curved scissors are required in this next step. Elevating the skin with atraumatic forceps or skin hooks, the surgeon uses the fine scissors to dissect the fat packet from Scarpa's fascia underneath the skin side of the flap. Starting at the medial 10-mm trocar site (the first 2.5-cm incision), the dissection of the fat plane from the under surface of Scarpa's fascia extends superiorly along the medial aspect of the limit of dissection as far as the surgeon can see, and then extends laterally toward the second 2.5-cm incision that was placed inferiorly in the center of the lower limit of dissection. Care should be taken to avoid creating a hole in Scarpa's fascia and the skin. Using the curved side of the fine scissors with the tips pointed down will help in the dissection and decrease the chance of creating a skin hole during this part of the procedure. The laparoscope is a ready source of excellent illumination for the dissection and is more effective than overhead lights or head lamps. The developing node and fat packet will be dissected from Scarpa's fascia connecting the two trocars and extending as far superior as possible, given the limits of visualization, but usually 5–6 cm.

Attention is next directed towards finding the deep limits of dissection. This is an easier plane to exploit than that between the skin and Scarpa's fasica. At the inferior limit of the dissection, the nodal and fat packet is divided along the inferior margin or limit of dissection, and posteriorly to expose the external oblique aponeurosis and fascia lata. Once this plane has been developed it can quickly be advanced from the initial 2.5-cm incision site towards the second 2.5-cm incision site using the 5- or 10-mm LigaSure (Covidien, Boulder, CO, USA) bipolar cautery device to divide any perforating vessels. Once the inferior limit has been freed from the underlying fascia along the inferior margin of dissection, the same plane is dissected superiorly for 5–6 cm using the laparoscope to illuminate the field and the LigaSure for hemostasis. The dissection is then extended along the medial and lateral marked limits of dissection, progressively freeing the packet towards the upper or superior margins of dissection. This will help to expose the saphenous vein medially, which should be spared if possible.

Once the dissection has freed the packet from the lateral, medial, and inferior borders for a distance of 5–6 cm, a short 5-mm threaded trocar is placed in the lateral position (Figure 78.2) using the surgeon's finger as a guide. The two 10-mm blunt tipped trocars (Covidien) can now be placed in the two inferior 2.5-cm incisions, the balloons inflated, foam collars lowered into place to create an air-tight seal, and the insufflation tubing attached to the (noncamera) trocar. The blunt tipped trocar is ideal for this procedure since its unique internal balloon and foam collar create an excellent seal, while leaving a very small profile inside the area of dissection. The camera is placed through the middle inferior trocar site (Figure 78.2). The medial 10-mm trocar will become the working trocar, since it can accommodate a retrieval sac and larger instruments, such as the laparoscopic spoon forceps, to remove lymph node packets during the procedure.

The working space is insufflated to a pressure of only 5 mmHg. Higher pressures will not aid in the dissection but will result in subcutaneous spread of CO_2.

The 5- and 10-mm LigaSure devices are used to dissect the node packet. The bipolar device results in less visual obstruction compared to the water vapor emitted by ultrasonic shears, and consequently allows the dissection to proceed with fewer interruptions to clean the camera lens.

Dissection

Inguinal lymph nodes are divided into superficial and deep nodes. The superficial nodes are those located anterior to the fascia lata and the deep nodes are those located posterior to the fascia lata. The inguinal lymph node dissection is carried out 2 cm above the inguinal ligament superiorly, lateral to the sartorius muscle and medial to the adductor longus. The superficial nodes are located in four quadrants centered around the saphenofemoral junction: (1) nodes in the area of the superficial circumflex iliac vein; (2) nodes in the area of the superficial epigastric vein and the superficial external pudendal vein; (3) nodes located in the inferomedial quadrant around the saphenous vein; and (4) nodes around the insertion of the superficial circumflex iliac vein and the lateral accessory saphenous vein (Figure 78.3) [6].

The deep inguinal lymph nodes include the most cephalad node, known as the node of Cloquet, located in the area of the femoral vein and the lacunar ligament (Figure 78.4).

The dissection begins above Scarpa's fascia, anteriorly removing the tissue located between the skin and the fascia lata. Early in the dissection, the saphenous vein should be identified and preserved. If possible it is helpful to identify the borders of dissection medially at the adductor longus and laterally at the sartorius muscle edges. In some patients it can be difficult to identify these landmarks without opening the fascia lata, but the margins marked on the skin will help in the dissection of the superficial nodal tissue. Subcutaneous vessels and saphenous branches can be divided using ultrasonic

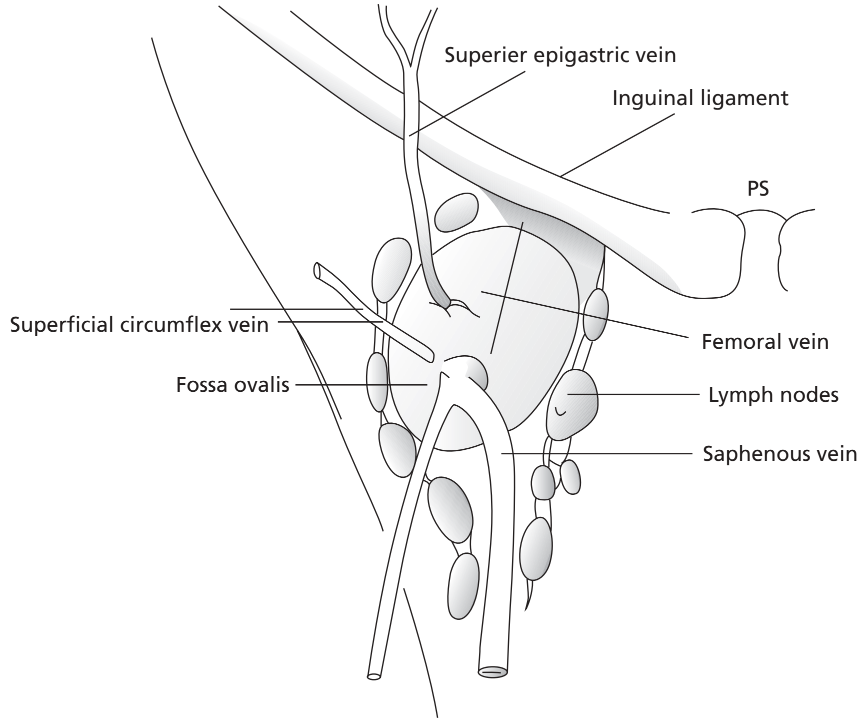

Figure 78.3 Location of superficial nodes in four quadrants centered around the saphenofemoral junction (see text) (reproduced from Bishoff J.T., Kavoussi, L.R., eds. *Atlas of Laparoscopic Urologic Surgery.* Philadelphia: Saunders Elsevier, 2007, with permission).

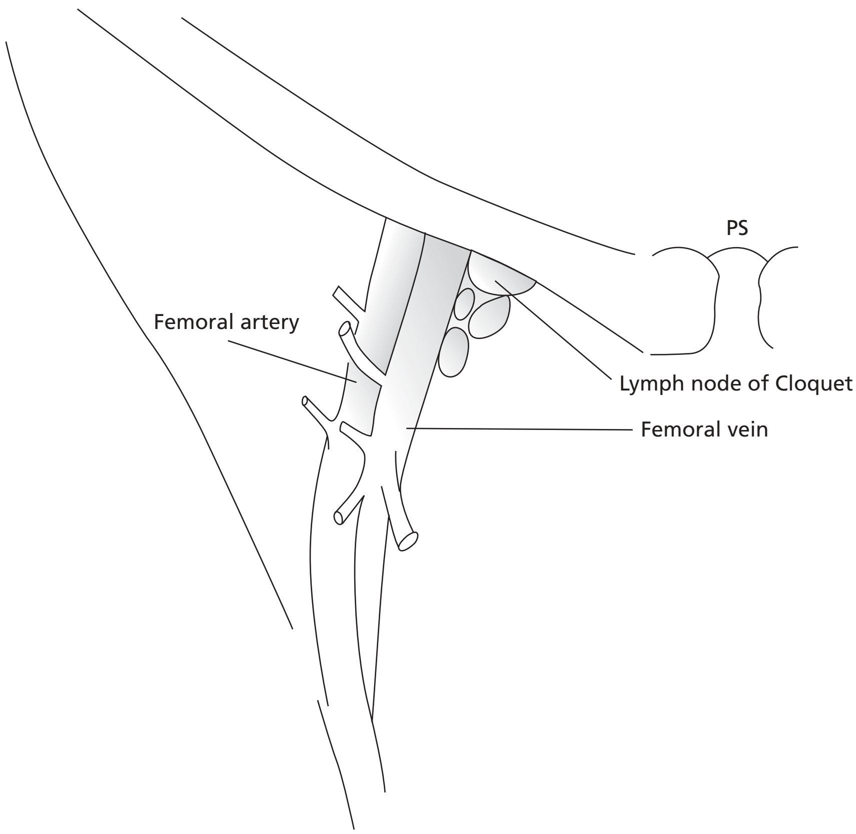

Figure 78.4 Location of the node of Cloquet. PS, pubic symphysis (reproduced from Bishoff J.T., Kavoussi, L.R., eds. *Atlas of Laparoscopic Urologic Surgery.* Philadelphia: Saunders Elsevier, 2007, with permission).

energy or electrocautery. Lymph node-bearing tissue is dissected from the fascia lata to the fossa ovalis.

As the dissection progresses towards the inguinal ligament, the external ring is identified and the fat and lymphatics in the area of the cord to the base of the penis medially are removed. The lymph node dissection is continued for 3–4 cm superior to the inguinal ligament. Once the nodal tissue and fat are removed from the external oblique and the inguinal ligament, the femoral vessels will be identified inside the femoral sheath.

To gain access to the deep nodes, the fascia lata is opened to the edge of the adductor longus medially and the sartorius muscle laterally. The triangular-shaped lymph packet within the femoral triangle is carefully removed. Opening the femoral sheath down towards the apex of the triangle will reveal the deep lymph nodes. Medial dissection will free the node of Cloquet. Any residual tissue between the femoral artery and vein is removed. Care is taken to prevent injury to the femoral nerve by limiting the lateral dissection to the femoral artery.

If the skin overlying the exposed vessels appears to be compromised in any way, the sartorius can be mobilized from the anterior superior iliac crest, using ultrasonic or bipolar cautery, and transferred over the exposed vessels. Three or four size 2-0 PDS sutures are used to attach the sartorius muscle to the inguinal ligament.

The lymph node packet can be too large to extract through the initial skin incision. In this case the packet can be divided using the bipolar cautery device and extracted in two long strips. We recommend placing the nodes in an extraction sac to decrease the chance of inadvertent skin contamination. If a large nodal packet is placed in the extraction sac but cannot be extracted through the trocar, the balloon on the trocar can be deflated and the packet (secured inside the retrieval bag) can be extracted directly through the incision. In order to prevent seeding the trocar site, fatty and lymphatic tissue specimens should not be extracted directly through the skin incision without being placed inside an extraction sac. In the case of large specimens, the packet can be divided into two long strips for extraction.

At the end of the procedure a 7-mm Jackson–Pratt drain is placed inside the cavity to ensure drainage at the most dependent site of dissection. This can be placed through the 5-mm trocar site or a new site chosen as needed. The two 10-mm trocar sites are closed with skin adhesive or subcuticular sutures. Once the skin adhesive is dry, a circular bandage is placed around the surgical area and held in place with an elastic bandage for 24 h.

Table 78.2 Minor and major postoperative complications.

Minor
Local wound debridement in clinics
Mild-to-moderate leg edema
Seroma formation not requiring aspiration
Minimal skin edge necrosis requiring no therapy
Scrotal edema
Major
Wound infection
Severe leg edema interfering with ambulation
Skin flap necrosis requiring skin graft
Deep venous thrombosis
Re-exploration or other invasive procedure performed in the operating room
Death

Postoperative management

The patient is discharged the day after surgery. Waist-high elastic stockings are worn for 2 weeks. Bed rest at home is recommended for 5–7 days with the lower extremities elevated. Low molecular weight heparin (Lovenox; Sanofi-Aventis, Bridgewater, NJ, USA) is started after surgery and continued until the patient is fully ambulant and the drain has been removed. The subcutaneous drain remains in place until daily output is less than 30 mL.

Complications

The diagnostic and therapeutic benefits of early inguinal lymphadenectomy should be measured against the potential morbidity associated with the procedure [7, 8]. Patients should be aware of the minor and major post-operative complications associated with this procedure (Table 78.2).

CHAPTER 79

Laparoscopic Retroperitoneal Lymph Node Dissection

Thomas J. Guzzo[1] & Mohamad E. Allaf[2]

Introduction

Testicular cancer is the most common malignancy in men aged 15–35 years [1]. Fortunately, survival rates for men with testicular cancer are excellent, largely based on a multidisciplinary treatment approach incorporating surgery, radiation and cisplatin-based chemotherapy. Retroperitoneal lymph node dissection (RPLND) has an important diagnostic and therapeutic role in the management of men with testicular cancer. Although RPLND is used in the management algorithm for seminoma patients with residual positron emission tomography (PET)-positive masses following chemotherapy, the overwhelming majority of RPLNDs are performed in patients with nonseminomatous germ cell tumors (NSGCTs) and therefore this patient population will be the focus of this chapter.

There is a well-defined treatment algorithm for patients with NSGCTs based on both stage and risk of disease recurrence [2]. Within this treatment paradigm, surgical management in the form of RPLND maintains a critical role. The rationale for RPLND in the management of NSGCTs includes a highly predictable pattern of lymphatic spread to the retroperitoneum, the potential for RPLND to be curative in patients with low-volume retroperitoneal disease, and the 20–30% false-negative rate in the radiographic staging of patients with clinical stage I disease [3].

Traditionally, RPLND has been performed by way of an open incision, with most preferring a midline approach. With the increasing popularity of minimally invasive surgery, surgeons have been expanding the application of such approaches to the treatment of more complex disease processes. Minimally invasive surgery offers the advantage of decreased blood loss, less pain, improved cosmesis, and shorter convalescence times; however, it should be noted that the oncologic efficacy of any cancer procedure is paramount and should not be compromised in an effort to expand the application of minimally invasive surgery. With this in mind, it should be noted that open RPLND has proven excellent long-term oncologic outcomes, and therefore laparoscopic RPLND should be performed with the goal of improving patient quality of life, while replicating the oncologic efficacy of the open approach.

Laparoscopic RPLND has not gained widespread acceptance as readily as other minimally invasive urologic procedures, such as laparoscopic nephrectomy and robotic prostatectomy. The rationale for this is likely twofold. First, laparoscopic RPLND is a technically demanding operation which requires dissection around major vascular structures and therefore is limited to those with extensive laparoscopic experience. Second, laparoscopic RPLND was used as a staging procedure in many initial reports without attempting to replicate the open technique. In such series, RPLND was aborted in favor of chemotherapy if positive lymph nodes were encountered and thus was performed for staging purposes [4–6]. As laparoscopic skills have evolved, techniques for laparoscopic RPLND have also matured. Laparoscopic RPLND is now being performed within specialized centers with therapeutic intent; with bound-

Smith's Textbook of Endourology, Third Edition. Edited by Arthur D. Smith, Gopal H. Badlani, Glenn M. Preminger, Louis R. Kavoussi.

aries of dissection identical to those of the open approach.

Rationalein patients with Stage I and II nonseminomatous germ cell tumors

Despite negative cross-sectional imaging, 25% of patients with stage I NSGCT will harbor occult malignancy in the retroperitoneum [3]. RPLND can accurately stage the retroperitoneum, identifying patients with metastatic disease despite negative imaging. The vast majority (>90%) of patients with pathologic stage I disease will be cured with RPLND alone. In patients with a low tumor burden, RPLND spares patients the toxicity and potential long-term morbidity of systemic chemotherapy [7]. The retroperitoneum is also the most frequent site of chemoresistant malignant germ cell tumor and teratoma, both of which can be effectively controlled with RPLND [8, 9]. RPLND is also advocated in men with teratoma in the orchiectomy specimen, as this may increase the likelihood of retroperitoneal teratoma which is chemoresistant [8, 9].

Patients with clinical stage II NSGCTs can also benefit from RPLND. Patients with stage IIa disease can potentially forgo additional treatment in the form of chemotherapy as up to 70% will be cured with surgery alone [10]. The risk of relapse following RPLND is directly related to the extent of disease found in the retroperitoneum. Patients with pN2 or pN3 disease have relapse rates of 50% and therefore adjuvant chemotherapy should be strongly considered in those patients [11].

Templates

Retrograde ejaculation is a significant concern for young men who undergo RPLND. Earlier outcomes with non-nerve-sparing bilateral RPLND reported significant retrograde ejaculation rates. The relatively predictable and consistent pattern of lymphatic spread of testicular tumors, along with mapping studies to identify the most common areas of retroperitoneal metastasis, led to the concept of RPLND templates in an attempt to minimize the potential for retrograde ejaculation [12–14]. Such templates minimize dissection in retroperitoneal areas in which metastatic disease would be unlikely. Unilateral templates avoid dissection below the level of the inferior mesenteric artery, minimizing sympathetic nerve fiber damage in this region. Avoidance of dissection of efferent sympathetic fibers emanating from the contralateral sympathetic trunk also reduces the risk of retrograde ejaculation. Antegrade ejaculation is reported in approximately 90% of patients undergoing modified template RPLND [15, 16].

With further improvements in surgical technique, nerve-sparing techniques have been employed. The sympathetic trunks, postganglionic sympathetic nerve fibers, and hypogastric plexus can be prospectively identified at the time of RPLND and preserved. In doing so, ejaculatory function can be preserved in approximately 95% of men undergoing this procedure [17]. This technique offers the advantage of a bilateral dissection without compromising ejaculatory function and has replaced the use of template dissections at some centers.

Stage I nonseminomatous germ cell tumors

Critics of laparoscopic RPLND cite early series which used this technique as a staging procedure without intention of replicating open RPLND. In the setting of metastatic disease, laparoscopic RPLND was aborted and patients were given chemotherapy. Contemporary laparoscopic series have moved towards replicating open RPLND both in its therapeutic intent and extent of dissection. This includes the use of bilateral dissections, retroaortic/retrocaval lymphadenectomy, and limiting the use of chemotherapy in patients with low-volume stage II disease. While adhering to strict oncologic principles, laparoscopic RPLND offers the advantage of decreased patient morbidity.

Early and intermediate outcomes for laparoscopic RPLND have been reported from multiple centers (Table 79.1) [18–23]. These studies confirm that laparoscopic RPLND is feasible and safe. Open conversion rates have proven to be low, with uncontrollable bleeding being the most common reason for conversion to an open procedure. Mean operative times range from 138 to 261 min, with mean length of stay ranging from 1.6 to 6 days. Mean blood loss range from 50 to 145 mL. For patients with pN0 disease, retroperitoneal recurrences are rare when laparoscopic RPLND is performed with therapeutic intent. The long-term oncologic efficacy of laparoscopic RPLND remains to be proven. As discussed previously, the significant majority of patients from initial laparoscopic RPLND series received adjuvant chemotherapy and therefore the oncologic efficacy of the surgical procedure cannot be determined. More contemporary series have reported outcomes for patients found to have node-positive disease at the time of therapeutic laparoscopic RPLND with promising early results. In the three series in which chemotherapy was not administered to node-positive patients, there have been no recurrences within the boundaries of the RPLND template. Skolarus *et al*. reported one patient in their series with pathologic stage IIA disease who had no evidence of disease 31.3 months following laparoscopic RPLND [22]. Nielsen *et al*. reported on 10 pathologic stage IIA patients who were observed without chemotherapy after laparoscopic RPLND. Recurrences were seen in two (20%) patients (one biochemical, one

OR, operating room; EBL, estimated blood loss; NR, not reported; RP, retroperitoneal.

pulmonary) following laparoscopic RPLND and were salvaged with chemotherapy. The remaining eight patients were without evidence of disease at a mean follow-up of 37 months [19]. Guzzo *et al*. have also reported on four patients with pN1 disease who did not receive adjuvant chemotherapy and who were without evidence of disease at a mean follow-up of 23 months [23]. More recently, Steiner *et al*. have reported their experience with bilateral nerve-sparing laparoscopic RPLND in 21 clinical stage I NSCGT patients, five (24%) of whom were found to have pathologic stage IIA disease [24]. None of the five patients was given adjuvant chemotherapy and all were without recurrence at follow-up intervals of 2–35 months. Additionally, no retroperitoneal recurrences were noted in patients who had pathologically confirmed stage I disease, implying that an adequate dissection was performed.

Clinical stage II nonseminomatous germ cell tumors and post chemotherapy

Limited evidence exists regarding the role of laparoscopic RPLND for patients with stage II disease. Several studies have reported outcomes for laparoscopic RPLND in the postchemotherapy setting. Albqami *et al*. have reported their experience with 59 patients with stage IIB or IIC disease who have undergone postchemotherapy laparoscopic RPLND [20]. No open conversions were reported in this patient population. Of the 43 patients with preoperative stage IIB disease with a mean follow-up of 53 months, one experienced a recurrence 24 months postoperatively along the external iliac nodes, outside the original template. Maldonado-Valadez *et al*. have also demonstrated the feasibility of postchemotherapy laparoscopic RPLND in a small number of patients (n = 16), reporting no open conversions or blood transfusions [25]. Viable tumor was found in three (19%) patients, of whom two received additional adjuvant chemotherapy. Of concern, two patients with viable tumor experienced a recurrence. The first was noted to have an enlarged renal hilar lymph node at his first 3-month postoperative follow-up. This was managed with repeat laparoscopic RPLND and the final histology revealed only necrosis. The second patient had a retroperitoneal recurrence 11 months postoperatively and ultimately died of his disease despite salvage chemotherapy. These two series are concerning from an oncologic perspective given the fact that a full bilateral RPLND was not performed [20, 25], which is generally considered standard of care in the postchemotherapy setting for NSGCT patients [26]. Although these authors reported that postchemotherapy RPLND was safe,

others have reported open conversion rates as high as 29% and 67%, and overall complication rates greater than 50% [5, 27]. Given the high potential for complications in postchemotherapy patients, laparoscopic RPLND should only be attempted in highly selected patients by surgeons with significant laparoscopic experience who are comfortable with open RPLND if conversion is needed.

Keeping in line with the goals of open postchemotherapy RPLND, Steiner *et al*. have performed bilateral nerve-sparing laparoscopic RPLND on 19 postchemotherapy patients with stage IIB disease [24]. The authors found teratoma, necrosis/fibrosis, and active tumor in four, 14, and one patient, respectively. Laparoscopic RPLND was also performed in two patients with clinical stage IIA disease who did not undergo chemotherapy. No retroperitoneal recurrences were noted in either group at 17 months follow-up.

Surgical technique

Laparoscopic RPLND is a technically demanding procedure and therefore should only be performed by surgeons experienced in complex laparoscopic surgery. Additionally, experience with laparoscopic vascular techniques and open RPLND is also advised in case of inadvertent vascular injury or the need for open conversion arises.

Preoperative patient preparation

Appropriate preoperative counseling should include all options for management, including open RPLND, chemotherapy, and surveillance when appropriate. Preoperative sperm banking should be discussed prior to surgery. The potential for open conversion either in the setting of intraoperative complication or extensive disease should also be discussed prior to surgery. Some surgeons recommend a low-fat diet 1–2 weeks prior to surgery to reduce the risk of chylous ascites; however, evidence for such an approach is lacking. Patients should be placed on a clear liquid diet 48 h prior to surgery and undergo a mechanical bowel preparation the day prior to surgery. Preoperative antibiotics are given prior to surgery, and antiembolism compression stockings and sequential compression devices are placed on the lower extremities to minimize deep vein thrombosis.

Positioning and port placement

General endotracheal anesthesia is required, as the patient must remain paralyzed throughout the case. Prior to insufflation, an orogastric tube and Foley catheter should be placed. The patient can be placed in the modified flank (similar to that for laparoscopic nephrectomy) or supine position. We prefer to place patients supine with both arms tucked, as this does not require repositioning if a bilateral RPLND is needed. All pressure points should be padded to minimize the risk of nerve palsy. Patients should be secured to the operating room table both with a seat belt and tape as the table is often maximally rotated to either side to facilitate bowel retraction (Figure 79.1).

A transperitoneal approach is the preferred method due to the larger and more anatomically familiar working space for most urologists. A retroperitoneal approach can be performed; however, doing so precludes bilateral

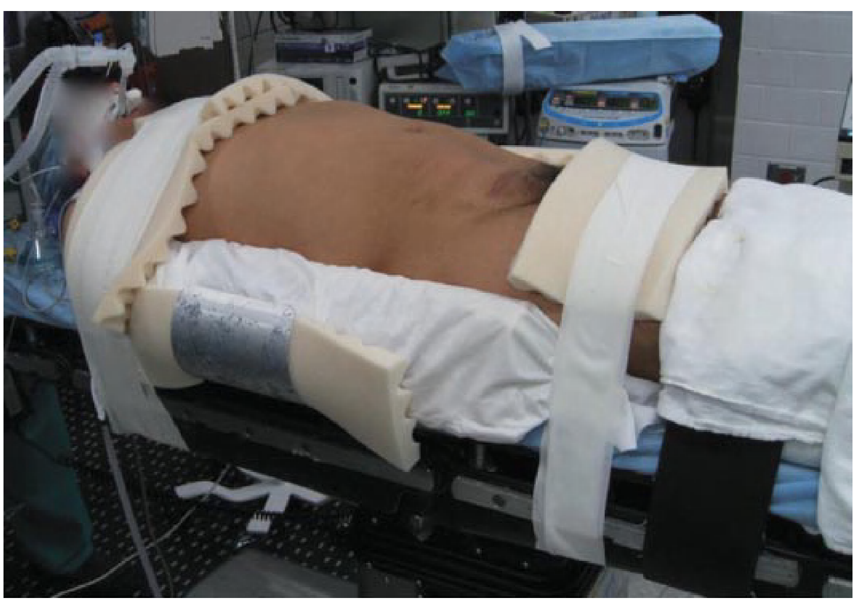

Figure 79.1 Supine positioning for laparoscopic retroperitoneal lymph node dissection.

dissection from the same port placement [28, 29]. Using a transperitoneal approach, peritoneal access is obtained via either Veress needle placement or Hasson technique. The peritoneal cavity is then insufflated to $15\,\text{cmH}_2\text{O}$ at which point four evenly spaced 10/12-mm laparoscopic ports are placed in the midline. The most superior port should be placed approximately 2 cm below the xiphoid process. It is important to maintain uniform spacing between the ports and thus a trocar may not always be located at the level of the umbilicus, depending on patient body habitus. A 10/12-mm port should be used for each site to allow instrument versatilty from a variety of working angles to cover the entire retroperitoneum. Once all ports are in place, the bed is rotated to assist in medialization of the bowel.

Right-sided dissection

The white line of Toldt is incised in a manner similar to that for a laparoscopic nephrectomy. The peritoneal incision is carried further inferiorly in order to completely expose the inferior border of the RPLND template and the spermatic cord. The duodenum is then kocherized, allowing for wide exposure of the retroperitoneum and great vessels. The ureter should be identified early during the course of dissection to minimize inadvertent injury.

The spermatic cord dissection is generally performed using the three most inferior ports, placing the camera in the middle. The peritoneum is incised medial to the spermatic cord and the vas deferens is transected to allow further mobilization. It is useful to place a clip on the gonadal vein proximally, which will minimize blood loss in the event of inadvertent avulsion. The spermatic cord can then be grasped and dissected inferiorly toward the internal ring. The peritoneum is then incised circumferentially around the internal ring. Retraction of the spermatic cord exposes fibrous attachments and greatly aids dissection. The dissection is carried inferiorly until the orchiectomy suture is encountered. The entire distal spermatic cord is then excised. The cord can then be followed proximally to the inferior vena cava (IVC) and ligated. The specimen can then be placed in an EndoCatch bag to be retrieved at the end of the case (see Video 79.1).

In general the right-sided template involves removal of the right common iliac, paracaval, interaortocaval, preaortic, and medial para-aortic lymph nodes. The lymphadenectomy is best started using the superior three ports with the camera port in the middle. Bowel mobilization can be greatly aided by placing a paddle retractor through the most inferior port, which can be held by the assistant surgeon. The tissue overlying the IVC is carefully incised longitudinally, allowing for a split and roll technique (see Video 79.2). A combination of blunt and sharp dissection can be used to carry this plane inferiorly over the common iliac vessels and superiorly to the renal hilum. Attention should be paid to the presence of lower pole accessory renal arteries, which can cross the IVC anteriorly. All fibroadipose tissue is then dissected free from the renal vessels to the junction of the IVC. The lateral extent of this packet is dissected free to the ureter and then followed down to the common iliac vessels. This packet can then be clipped and divided at the junction of the iliac vessels and placed in an endoscopic bag.

The medial border of the previously incised tissue of the IVC is then grasped and "rolled" medially the entire length of the infrahilar IVC. In doing so, the retrocaval space is exposed and dissected. Cautious dissection is important at this point to identify lumbar veins, which are clipped and divided, allowing for complete mobilization of the IVC and dissection of the posterior lymphatic packet. Lumbar vessels should be clipped, leaving space along the IVC between the clip in the event that a clip is displaced (see Video 79.3). In doing so, the vessel can be grasped on the caval side and controlled to avoid hemorrhage. Uncontrolled lumbar vessels that retract into the iliopsoas can generally be controlled with pressure and a figure-of-eight suture. If a bilateral RPLND is being performed, the postganglionic nerve fibers should be identified and dissected free from the lymph node packet prior to its release. Next the aorta is identified and the anterior tissue is split in a similar fashion to that of the IVC to the level of the inferior mesenteric artery (IMA) inferiorly and the renal hilum superiorly. The interaortocaval node packet is then rolled medially and completely dissected free (see Video 79.2). Finally, the para-aortic node packet is dissected to the level of the IMA, completing the dissection.

Left-sided dissection

Similar to the right-sided dissection, the white line of Toldt is taken down sharply. It is important to completely free up the lateral attachments of the spleen to obtain wide exposure of the retroperitoneum. The distal spermatic cord dissection is performed in a similar fashion to that of the right-sided technique. The spermatic cord can then be dissected proximally to its insertion in the left renal vein and ligated. If necessary, lumbar veins draining into the renal vein can be clipped and divided in order to achieve complete renal hilar dissection. The renal vein can then be followed to its insertion into the IVC, removing all nodal tissue. The renal artery is also completely dissected. It is advisable to use clips in the area of hilar dissection to minimize the risk of postoperative chylous ascites.

The tissue overlying the aorta is then split as described above for the right-sided dissection. If nerve sparing is intended, care should be taken to identify the postganglionic sympathetic nerves overlying the aorta, which can be dissected free from the nodal packet (see Video 79.4). Laterally, the ureter is identified and all lymph node tissue is removed from its border down to the common iliac vessels. The previous split preaortic packet can then be rolled medially. With medial mobilization of this packet, the lumbar arteries will be encountered, which can be clipped and divided, allowing for dissection of the retroaortic space. As detailed previously, the tissues over the IVC can then be split to allow dissection of the paracaval, precaval, and interaortocaval lymph node packets.

Lymph nodes can be placed in a laparoscopic sac during the course of the operation. We typically place each lymph node packet in a separate laparoscopic sac; however, the use of multiple endoscopic retrieval sacs does add cost to the procedure. With the dissection complete, the retroperitoneum should be irrigated and hemostasis ensured. If large lymphatic leaks are identified, they should be ligated with clips. The bowel and adjacent organs should be inspected prior to closing the laparoscopic ports. The endoscopic bags can generally be retrieved through the trocar sites without having to extend the fascia. The trocar sites can then be closed using a laparoscopic fascial closure device. We typically do not leave a drain.

Bilateral laparoscopic dissection

Bilateral dissection may be performed when necessary and can be usually undertaken without a change in patient positioning. When the side of the primary tumor is completed with the templates described, a small amount of tissue is left just medial to the contralateral ureter and inferiorly towards the common iliac vessels. These tissues are dissected free and a bilateral dissection is completed.

Postoperative care

Patients are managed immediately after surgery without gastric decompression. Subcutaneous heparin injection can be administered on the evening of surgery. Clear liquids can be started the evening of surgery and patients can be advanced to a regular diet on postoperative day 1. Postoperative tachycardia can occur due to sympathetic stimulation and can be managed expectantly [30]. If bowel function has returned, patients can be discharged the afternoon of postoperative day 1. Some surgeons recommend a low-fat diet for several weeks postoperatively to minimize the risk of chylous ascites.

Complications

Laparoscopic RPLND is a technically challenging procedure associated with a steep learning curve. When performed by experienced surgeons, open conversion rates and perioperative complications are acceptable. The most common reason for open conversion is uncontrollable bleeding or vascular injury [31–33]. In contemporary series, the open conversion rate is less than 5%; however, open conversion rates have been reported to be as high as 11.8% [18–23, 34]. Surgeons should be experienced with operating around major vascular structures and laparoscopic hemostasis techniques to minimize the need for open conversion at the time of laparoscopic RPLND. Several hemostatic maneuvers, including increasing the pneumoperitoneum pressure, laparoscopic sponge pressure, use of hemostatic agents, and laparoscopic suturing techniques can all be used to control bleeding in the event of inadvertent vascular injury. Conversion to an open procedure should not be viewed as a failure and surgeons should be comfortable with the open technique in case open conversion is required. Injury to major abdominal viscera has been reported, but is rare [18, 33]. Open conversion and vascular injury rates have been reported to be higher in the postchemotherapy setting due to significant fibrosis which can obliterate normal anatomic planes [5, 27, 33].

Postoperative complications have been reported at a rate of 9.4–25.7% in contemporary series [18–23]. Reported complications include chylous ascites, ileus, lymphocele, nerve injury, pulmonary embolus, *Clostridium difficile* colitis, retroperitoneal hematoma, and urinoma [33]. Retrograde ejaculation is a potential long-term source of morbidity for patients undergoing both open and laparoscopic RPLND. Fortunately, the rates of retrograde ejaculation have been consistently low with the laparoscopic approach and range from 0% to 4.8% [18–23]. The incidence of retrograde ejaculation is higher in postchemotherapy laparoscopic RPLND patients, again due to dense fibrotic reaction which makes dissection and preservation of the nerves extremely challenging.

There is little information regarding prospective quality-of-life (QOL) outcomes for patients undergoing laparoscopic RPLND. A decreased analgesic requirement and time to resumption of oral intake has been reported in laparoscopic RPLND patients compared to those undergoing an open procedure [35]. This same cohort of patients also returned to their preoperative baseline QOL scores significantly faster than those undergoing open RPLND.

Conclusions

Laparoscopic RPLND has been demonstrated to be a feasible, safe, and effective treatment option for men

with clinical stage I NSGCT at large volume institutions with experienced laparoscopic surgeons. Laparoscopic RPLND has evolved into a therapeutic operation duplicating the open procedure, with early reports demonstrating efficacy and minimal morbidity. Data regarding laparoscopic RPLND for clinical stage II disease and for patients who have received chemotherapy are limited and larger cohorts of patients with longer term follow-up are required to define the exact role of laparoscopic RPLND in this setting.

CHAPTER 80
Laparoscopic Varicocelectomy

Duong Tu & Kenneth I. Glassberg

Division of Pediatric Urology, Morgan Stanley Children's Hospital of New York-Presbyterian, Department of Urology, Columbia University, College of Physicians and Surgeons, New York, NY, USA

Introduction

Varicoceles have been associated with progressive deterioration of testicular function and testicular hypotrophy. This is duration dependent and varicocele repair can stop or reverse this progression [1–6]. Most of the early scientific literature focused on infertility in adults; however, pediatric varicoceles are often identified by their physical appearance, e.g. the "bag of worms," during investigation of size asymmetry, or as incidental findings on examination or sonographic evaluation for other reasons. Pain is a much more common presentation in adults as compared to adolescents. Correction of varicoceles in the adolescent population has centered on asymmetric testicular growth. Correlations have been suggested between testicular hypotrophy and sperm concentration and motility [7, 8], and the logical assumption is that this affects future fertility.

Varicocelectomy has evolved over the years with three main approaches: microsurgical subinguinal (Goldstein), inguinal (Ivanissevich), and abdominal (Palomo, nonartery sparing). Intraluminal approaches, such as surgical antegrade sclerosis, which has been gaining in popularity particularly in Europe, and radiographic retrograde embolization, have also been utilized and studied. Laparoscopic varicocelectomy was introduced in 1990 [9] with more detailed description shortly thereafter [10–12]. Variations and refinements of the technique occurred over the ensuing years, and it was more frequently described in the pediatric literature.

One contentious issue is whether or not it is necessary to preserve the testicular artery. No significant difference has been found between artery-sparing techniques and the Palomo technique with regards to testicular growth [13, 14]. Some argue that the Palomo technique is associated with less persistence of varicoceles after repair due to the ligation of the small veins intimately associated with the testicular artery (0% vs 11%) [15]. Despite the higher recurrence associated with artery-sparing techniques, Zampieri *et al*. believe that preservation of the testicular artery leads to better improvement of semen parameters [16]. The results from initial series may reflect the limited access at the time to the higher definition, greater magnification laparoscopes, whereas now these are widely used to identify the accessory veins adherent to the artery. A recent addition to the armamentarium for artery-sparing varicocelectomy is a variety of Doppler transducers for laparoscopic use.

Sparing of the lymphatics (facilitated by laparoscopic magnification) has been shown to decrease the incidence of postoperative hydrocele formation [17, 18] compared to the similar open technique in subinguinal microscopic varicocelectomy [19–21]. Nonartery-sparing techniques have a higher incidence (~30%) of postoperative hydroceles because of lymphatic injury [14, 22, 23], although only 5% ultimately go on to require hydrocelectomy [14].

Advantages and disadvantages

The increased magnification afforded the surgeon with laparoscopy allows for accurate identification of vessels,

Smith's Textbook of Endourology, Third Edition. Edited by Arthur D. Smith, Gopal H. Badlani, Glenn M. Preminger, Louis R. Kavoussi.

lymphatics, which give rise to hydroceles if ligated, and the internal spermatic artery [17, 24]. In a recent analysis, laparoscopic varicocelectomy appeared to be safe in patients who had had prior inguinal surgery [25]. Suprainguinal access allows for high ligation of fewer veins compared to a more technically difficult and longer subinguinal microscopic approach. The laparoscopic approach offers a distinct advantage for bilateral varicoceles, as no additional incision is needed.

The main disadvantages of laparoscopic varicocelectomy are the same as those inherent to all laparoscopic surgery. Like all new techniques, there is a learning curve. How steep this learning curve is depends on the relative experience of the surgeon. For a surgeon already familiar with laparoscopic techniques, varicocelectomy using this approach is usually not difficult to master. The laparoscopic technique is more invasive than open varicocelectomy. Laparoscopic entry with the initial trocar for establishing the pneumoperitoneum runs the risk of perforation of major blood vessels, bowel, or bladder. Moreover, injury to the inferior epigastric vessels is a known risk with trocar placement. These risks are not associated with open varicocelectomy.

Anatomy [26]

The venous drainage of the testicle and epididymis can be divided into two systems. The predominant venous drainage system consists of the anterior spermatic or pampiniform plexus, responsible for draining the testis and anterior epididymis, and the testicular vein, which drains into the inferior vena cava on the right and the left renal vein on the contralateral side. The early branches of the testicular vein are the primary site of ligation in laparoscopic varicocelectomy.

An ancillary venous system is comprised of the posterior spermatic plexus or funicular veins, which drains the posterior epididymis, terminates in the inferior epigastric vein, and eventually empties into the external iliac vein, and the deferential veins that ultimately drain into the hypogastric vein via the superior vesical vein. In addition, the cremasteric or external spermatic vein drains into the saphenous system via the pudendal vein.

It should be kept in mind that there is a complex intercommunication between both the systems and the individual veins, and there exists substantial anatomic variation.

Indications

The indications for operative repair are persistent or recurrent scrotal pain, and as part of the treatment for subfertility. In adolescents, size discrepancies ranging between 10% and 20%, with the left testicle smaller than the right, have been proposed as cut-offs for significant asymmetry. In the pursuit of early treatment in adolescents with varicoceles to prevent the consequent development of infertility, recent evidence indicates that testicular asymmetry of greater than 20% or high peak retrograde venous flow of 38 cm/s or greater are prognostic indicators for persistent asymmetry and hence potentially abnormal semen analyses [27].

Operating room set-up

The patient should empty his bladder prior to entering the operating room. This avoids the need for urethral catheterization. He should be positioned supine on the operating room table. General anesthesia is induced. After adequately securing the patient to the table, the table is rotated 20–30° to elevate the affected side. Mild Trendelenburg will help allow the bowel to fall away from the pelvis.

The surgeon stands on the side contralateral to the side of the varicocele, and the assistant stands on the ipsilateral side.

The required instruments are listed in Table 80.1.

Trocar placement and technique

The landmarks for trocar placement are the umbilicus, pubic symphysis, and anterosuperior iliac spine.

Trocar placement for laparoscopic varicocelectomy involves many techniques incorporating anywhere from a single port [28] to three ports [29, 30]. The various approaches to access, such as transperitoneal versus retroperitoneal or closed versus open, are described in more detail in Chapters 74 and 75. Three-port transperitoneal access is described here (Figure 80.1), and we prefer to use the VersaStep™ Veress needle/radially expanding sheath system for initial access. This needle/sheath unit is passed through a curvilinear supraumbilical incision into the peritoneum (Figure 80.2).

Laparoscopic Doppler

Figure 80.1 Port placement: 5-mm supraumbilical trocar for camera and insufflation, 5-mm trocar half way between the umbilicus and pubic symphysis in the midline, and 5-mm trocar on the ipsilateral side of the varicocele, lateral to the epigastic vessels.

Figure 80.2 Veress needle/sheath placement into peritoneum through supraumbilical incision.

Once proper positioning is confirmed, the Veress needle is removed, leaving the sheath in place. A pneumoperitoneum of 15 mmHg is achieved, and the 5-mm trocar is advanced through the nonslip sheath. This serves as the laparoscope port. A 30° lens is inserted and under direct vision, a second 5-mm trocar is placed half to two-thirds of the way between the umbilicus and pubic symphysis in the midline. A third 5-mm port is placed on the side ipsilateral to the side of the varicocele and lateral to the epigastric vessels in line with the umbilicus.

In cases of bilateral varicocele, the positions of the trocar sites are the same for the first approached varicocele. For the contralateral side, the camera may be moved to the lateral port, if desired, and the two midline ports can serve as the working ports.

Exposure is obtained through the 5-mm supraumbilical port with the use of the 30° laparoscope to define the anatomy. The intrascrotal spermatic cord can be pulled to clarify the internal spermatic cord and its associated veins. By identifying and following the vas deferens, the internal ring is visualized (Figure 80.3).

The peritoneum wall is grasped proximal to where the vas deferens joins the cord (~5 cm) with the Maryland dissectors and the posterior peritoneum is incised with endoshears just anterolateral to the cord (Figure 80.4). The peritoneal window is extended inferiorly and medially.

A large vein is usually identified first anterolaterally (Figure 80.5). After isolating the vein with the Maryland dissector, it is ligated and divided using the LigaSure device (Figure 80.6). The use of this device avoids the need for multiple vascular staples to ligate each vein individually. Using two Maryland dissectors, any visible remaining veins are dissected while separating, if desired, the spermatic artery from them. These can be

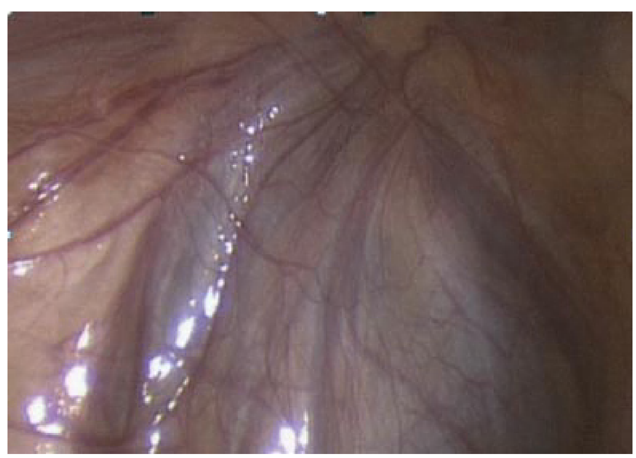

Figure 80.3 Visualization of the internal inguinal ring with convergence of the internal spermatic vessels (A) and vas deferens (B).

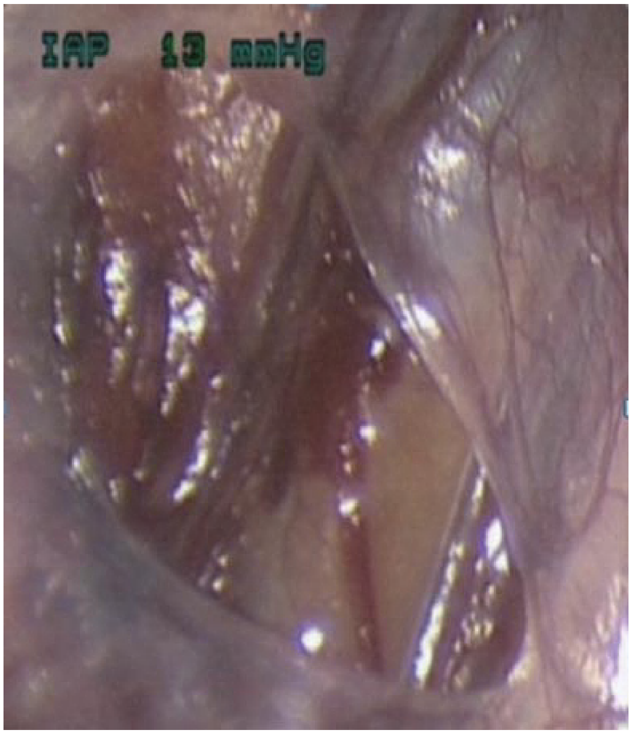

Figure 80.4 Incised posterior peritoneum.

ligated using the LigaSure device. The use of fulguration tends to spread to the fine lymphatics. The use of a laparoscopic Doppler may be helpful in identifying the artery (Figure 80.7). Often, the artery will not have a strong pulsation after manipulation. The Doppler probe can be used to help with the dissection as well (Figure 80.8). Under the superb magnification of the laparoscope, the lymphatic vessels can be identified as small, translucent vessels (Figure 80.9). These can be teased away from the vein bundles using two endoscopic dissectors.

The patient is returned to the supine position and evaluated for hemostasis. Any blood or irrigant that may have collected can be aspirated using the aspirator–irrigator. However, in most cases, this is not needed and therefore need not be routinely opened on the field.

Laparoscopic exit/port removal is performed under the direct vision of the laparoscope. Use of 5-mm ports avoids the need for fascial closure; however, we almost always close the supraumbilical and lower midline sites with a single absorbable suture. The patient is observed once more for hemostasis after efflux of pneumoperitoneum. The skin is closed with absorbable suture in a subcuticular fashion and sealed with a skin adhesive.

An alternative to the above trocar positioning is use of the long 5 mm trocar for the supraumbilical laparoscope port. The second 5 mm short trocar placed

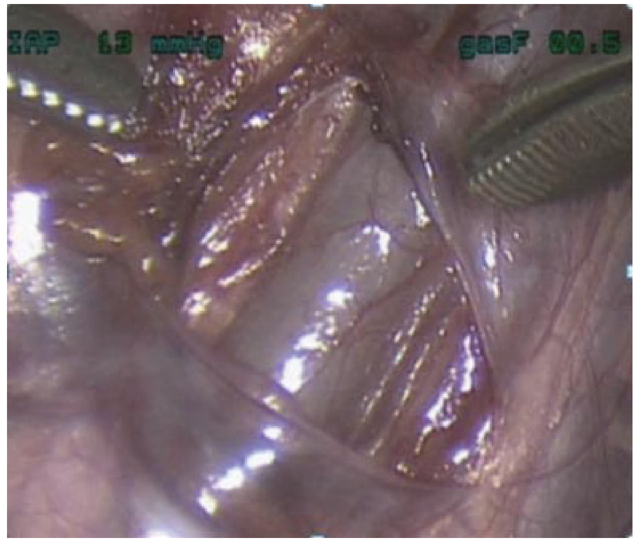

Figure 80.5 Large vein, anterolateral.

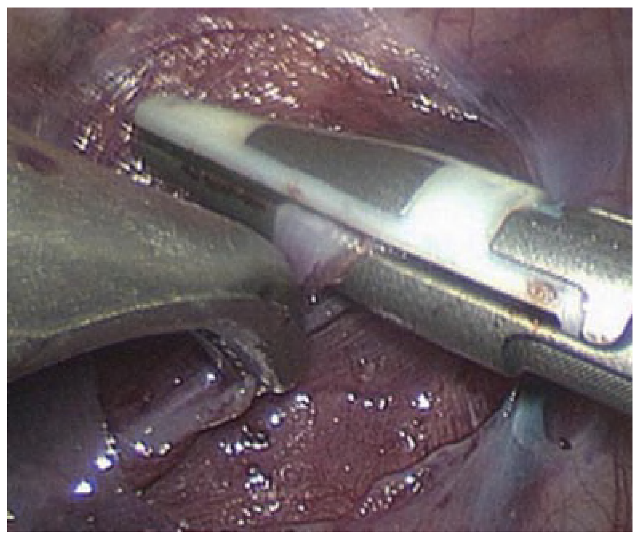

Figure 80.6 LigaSure™ device used to ligate and divide the vein.

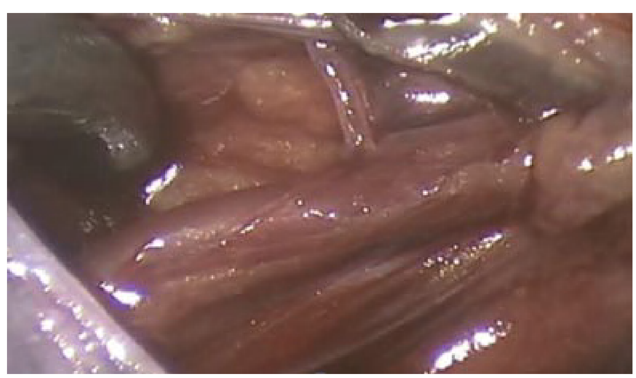

Figure 80.7 Spermatic artery.

half to two-thirds of the way between the umbilicus and pubic symphysis in the midline is equipped with a toilet seat type 3mm reducer cap to allow for use of smaller 3mm instruments (Maryland dissector and endoshears) in addition to the 5mm LigaSure device. The third port can be substituted with a 3mm port placed lateral to the epigastric vessels on the side ipsilateral to the varicocele as above but instead of in line with the umbilicus, it should be approximately midway between the two midline ports. This is necessary to allow for the shorter 3mm instruments to be within working distance of the surgical site.

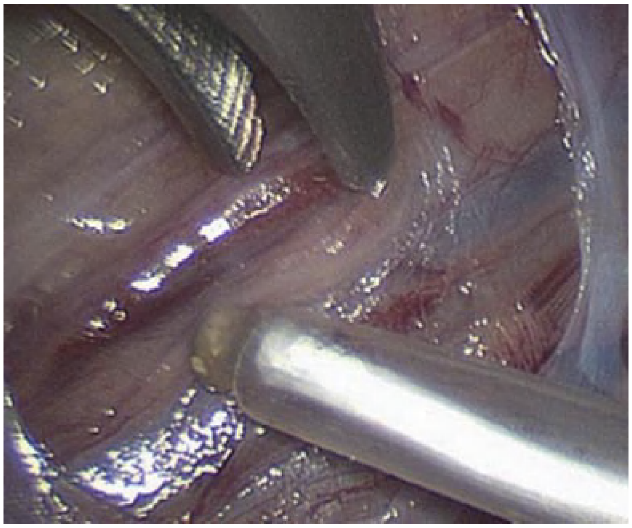

Figure 80.8 Doppler probe used for dissection and identification of the spermatic artery.

Complications

The main complications associated with laparoscopic varicocelectomy are postoperative hydrocele and varicocele recurrence (or perhaps, more accurately, persistence). The incidence of these two complications depends on whether the approach taken is artery sparing or non-artery sparing, and lymphatic sparing or *en masse* ligation. Other potential complications include bleeding, either from trocar placement (e.g. inferior epigastric vessel injury) or from the spermatic vessels. The use of the LigaSure device has significantly decreased the likelihood of inadequate ligation of these vessels and to date, we have not had any problems with delayed

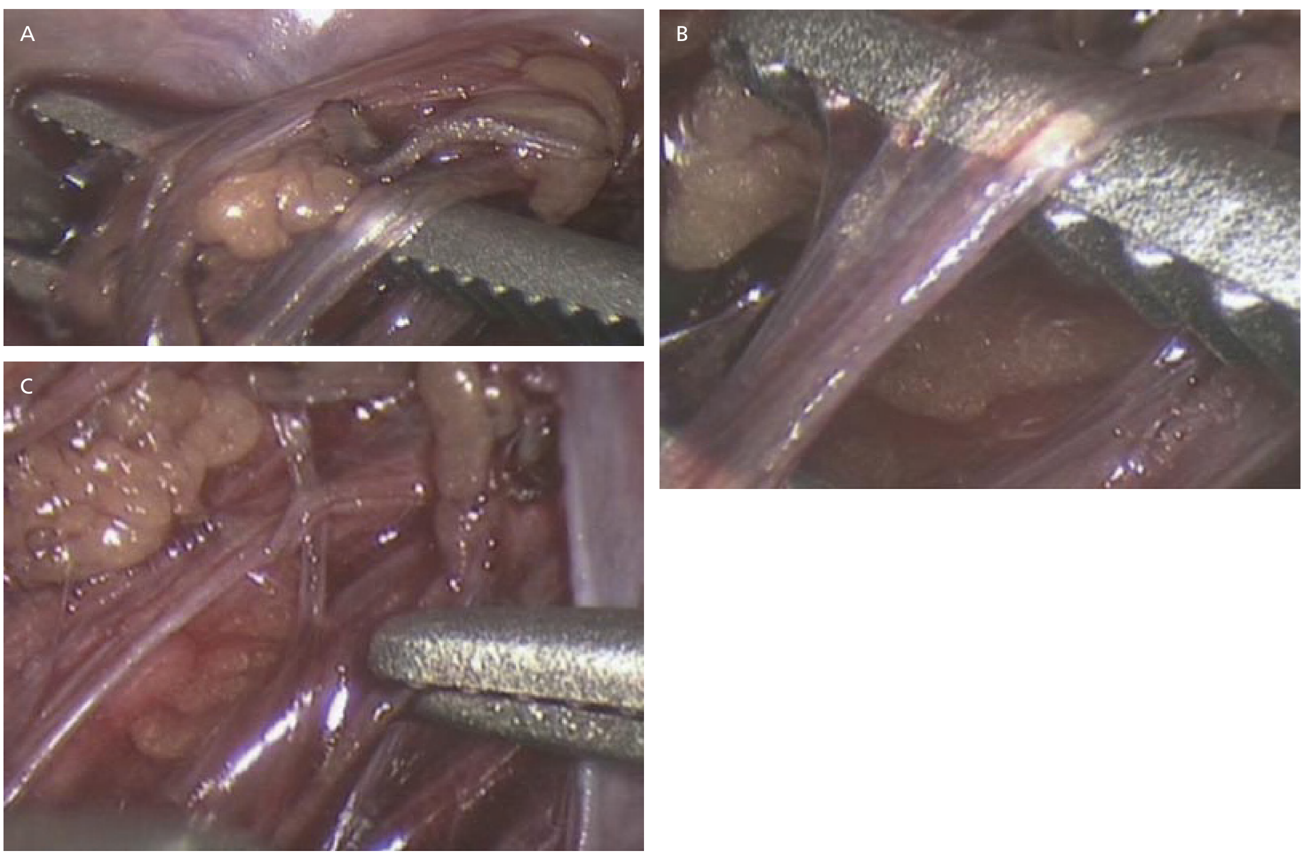

Figure 80.9 (A–C) Lymphatics as seen under magnification.

bleeding. Slight Trendelenburg allows gravity to retract the bowel away from the surgical field, possibly reducing the risk of injury from the surgical instruments.

Results

The true tests of success for varicocelectomy, regardless of approach or technique, are hydrocele formation and recurrence/persistence of varicocele. Initial reports have given variable results and have called into question the validity of using laparoscopy for the correction of varicoceles. However, there is evidence to suggest fewer wound complications, decreased testicular/scrotal edema, shorter operative time, and decreased need for postoperative analgesia using the laparoscopic approach. Podkamenev *et al*. randomized 654 patients to laparoscopic (434 patients) versus open varicocelectomy (220 patients), with both techniques using the Palomo technique of *en masse* ligation of the artery and vein above the internal inguinal ring with lymphatic preservation [31]., The groups were controlled for age, and varicocele side and grade (2–3). No statistical difference was found with regards to recurrence and hydrocele formation (<2%), but the differences in the following parameters were statistically significant: decreased genital edema, decreased length of stay (3 days for the laparoscopic group vs 7 days for the open group), decreased operating time (15 min vs 26 min), and decreased need for postoperative analgesia (14% vs 23%). McManus *et al*. evaluated 72 patients randomized to laparoscopic varicocelectomy (36 patients) and subinguinal microscopic varicocelectomy (36 patients). They showed a statistically significant difference in mean operative time (34 min for the laparoscopic group vs 60 min for the subinguinal microscopic group), hydrocele formation (8% vs 0%), and recurrence (0% vs 11%) [19]. Despite the 8% hydrocele formation rate, ultimately, only 2.7% required hydrocelectomy. Both these studies were limited by their relatively short follow-up time of approximately 6 months. We have noted that hydroceles and recurrences can sometimes present more than 1 year after repair.

Hydrocele (Table 80.2)

As discussed above, there is a high incidence of hydrocele formation (7–30%) with the Palomo technique [14, 18, 22, 23, 32], although a much smaller percentage actually require repair [14]. A decrease in incidence of hydrocele formation appears to correlate with sparing of the lymphatics, either with the microsurgical or laparoscopic technique, presumably because of the increased magnification and hence increased accuracy of identification with these techniques [17, 18] This explains why the *en masse* ligation associated with the Palomo technique renders such high rates of postoperative hydrocele. The rate of hydrocele formation in conventional (non-microsurgical) varicocelectomy has ranged from 3% to 14% [23, 33–35], whereas with the microsurgical approach multiple series have reported no occurrences [19, 33, 34, 36, 37]. Percutaneous procedures, which select for veins and not lymphatics, are not associated with hydrocele formation [38, 39].

Initial results of laparoscopic varicocelectomy showed the same problem as with conventional, i.e. non-microsurgical, open varicocelectomy and the Palomo method with respect to hydrocele formation, rates of which ranged from 11% to 20% [17, 24, 34, 40]. This can be explained by the fact that initial reports did not make use of the technologic advantage of laparoscopy and its role in preservation of the lymphatics [22, 40]. Our adoption of the lymphatic-sparing modification has given favorable results, with a decrease in the incidence of hydrocele formation from 11.4% to 3.4%, but no significant effect on the persistence or recurrence of varicocele [17]. A reduction in rate of hydrocele formation

Table 80.2 Rates of hydrocele formation and recurrence for different techniques.

Technique	Lymphsparing	Artery sparing	Hydrocele (%)	Recurrence (%)
Retroperitoneal/Palomo	No	–	7–30	0–4
Modified Palomo	Yes	–	0	2
Conventional Inguinal/Subinguinal	No	Yes		14
	No	No	3–14	13–14
Microsurgical	Yes	Yes	0	0–11
Laparoscopic	Yes	Yes	3	7–25
	Yes	No	1–4	0
	No	Yes	12	18
	No	No	11–20	0–9
Radiographic	Yes	Yes	0	5–22

from 17.9% to 1.9% has also been observed at another institution [24].

Recurrence (Table 80.2)

Feber and Kass reported on their 20-year experience with 312 patients who underwent the open Palomo procedure with a recurrence rate of 3.9% [14]. Others have reported similarly low rates of recurrence with the traditional and modified Palomo techniques [18, 23]. This is related to the nature of the Palomo technique wherein the artery is not spared, resulting in ligation of the veins that are intimately associated with the spermatic artery, as mentioned above [15]. Conventional inguinal/subinguinal approaches have had recurrence rates around 14% regardless of whether the artery was spared or not [18, 23, 34]. For the microsurgical approach, recurrence rates have ranged from 0% to 11% [19, 34, 37].

Low recurrence rates with sacrifice of the artery have also been seen with the laparoscopic approach. A recurrence rate of 7–25% was demonstrated with laparoscopic sparing of the artery, a rate that is intolerably high [24, 37, 40, 41]. However, in one series in which the laparoscopic surgery sacrificed the artery, the recurrence rate plummeted from 25% to 0% [41].

Finally, for the percutaneous/radiographic modality, May *et al*. reported superiority of laparoscopic varicocelectomy over antegrade sclerotherapy with regards to recurrence (4.9% vs 15.7%) with median follow-up of 59 months [39]. Another study found a recurrence rate as high as 22% for antegrade sclerotherapy [38]. Microcoil embolization appears to give a lower rate of recurrence (4.8%) [42].

Follow-up

Typically, we see our adolescent patients at 2 weeks, 6, 12, and 24 months following repair. We follow them by palpation and Doppler ultrasound, evaluating both peak retrograde flow and maximum vein diameter. We believe that any patient with some degree of residual venous backflow or dilation should be followed for longer than 2 years. In patients in whom the varicocelectomy was performed for infertility, follow-up should be longer.

Conclusions

Strict conclusions are difficult to draw based on the available literature due to the variability of technique, even when the approach, whether open, laparoscopic, or radiographic/percutaneous, is the same. As is the case with all evolving techniques, many series do not clearly indicate whether the artery or lymphatics is spared, making it difficult to interpret results regarding hydrocele formation or varicocele recurrence. The results discussed above were synthesized from the few articles that do remark on these specific details of the surgery. Even then, these results are mainly from case series and not randomized controlled studies. Moreover, the follow-up periods were widely variable. While some trends can be determined, further study is required.

Hydrocele formation appears to be dependent on whether the lymphatics are spared or not. Naturally, in order to spare the lymphatic channels, magnification either by the microscope or laparoscopy is necessary. The less than 5% rate of hydrocele formation in laparoscopy with lymphatic sparing is much better than the rates reported for Palomo and conventional varicocelectomy. However, it must be kept in mind that not all of these hydroceles require intervention. Laparoscopy does lose out to the 0% hydrocele formation rate with microsurgical and radiographic modalities, although this must be balanced against the almost doubled operative time in most hands for microsurgery and the high recurrence rate and specialization of the radiographic route.

Recurrence appears to be dependent on whether or not the artery is spared. Sacrificing the artery decreases the rate of recurrence significantly, and is precisely why the Palomo technique and its variations have such a low recurrence rate. However, sacrificing the artery laparoscopically can afford similarly low recurrence rates, while at the same time preserving the lymphatics, thereby keeping the hydrocele rate low, a goal the traditional Palomo technique has a problem achieving.

In conclusion, the optimum of low rates of hydrocele formation and of recurrence can be achieved with the microsurgical or laparoscopic routes. Laparoscopic varicocelectomy with sacrificing of the artery and preservation of the lymphatics can give results that are just as good, if not better, than microsurgical varicocelectomy, and is a viable option for patients with varicoceles.

CHAPTER 81
Renal Surgery for Benign Disease

Sean P. Hedican & Stephen Y. Nakada
Department of Urology, The University of Wisconsin School of Medicine and Public Health, Madison, WI, USA

Introduction

Benign renal disease processes represent an ideal application for the laparoscopic approach due to the significant morbidity associated with the large flank or subcostal incisions required for the corresponding open procedures. Improvements in the understanding of laparoscopic anatomy, instrumentation, and laparoscopic training have made many of these operations commonplace at both community and university centers. We outline the major procedures now being performed for benign renal diseases and provide a step-by-step guide for approaching these operations that we hope will prove useful for both experienced and inexperienced laparoscopic surgeons.

Indications

Simple nephrectomy

Laparoscopic simple nephrectomy is often far from "simple" even for the most experienced laparoscopic surgeon, because the conditions for which it is performed often result in significant perinephric scarring. The end result of these conditions is typically a kidney with marginal function and associated pain, hematuria, recurrent infections, or renovascular hypertension. Initiating conditions include chronic obstruction from an undiagnosed or inadequately treated ureteropelvic junction obstruction (UPJO), stone disease, extrinsic compression, or iatrogenic strictures of the ureter [1, 2]. Patients with persistent infections in poorly functioning kidneys from vesicoureteral reflux (VUR) or associated stone disease may require a nephrectomy to halt recurrence of the infectious process or pain associated with the condition. Similar symptoms may occur in patients with acquired renal cystic disease, autosomal dominant polycystic kidney disease (ADPKD), or multicystic dysplastic kidneys, ultimately necessitating removal. Atherosclerosis, fibromuscular abnormalities, or prior trauma to the renovascular system can result in a poorly functioning renal unit associated with renin-mediated hypertension not alleviated by medical management. This condition requires surgical removal of the affected side in order to control blood pressure. A large angiomyolipoma not amenable to a partial nephrectomy would be another condition for which laparoscopic simple nephrectomy could be considered. Xanthogranulomatous pyelonephritis (Figure 81.1) and renal tuberculosis are two infectious conditions of the kidney that are relative contraindications to laparoscopic removal, as will be discussed later.

Heminephrectomy

Laparoscopic removal of an upper or lower pole moiety is performed for certain benign disease processes in kidneys with a complete duplication of the collecting system. Upper pole obstruction and a differential decline in function most commonly occur in association with an ectopic ureter, with or without associated reflux, or an obstructing ureterocele [3, 4]. Isolated loss of lower pole

Smith's Textbook of Endourology, Third Edition. Edited by Arthur D. Smith, Gopal H. Badlani, Glenn M. Preminger, Louis R. Kavoussi.

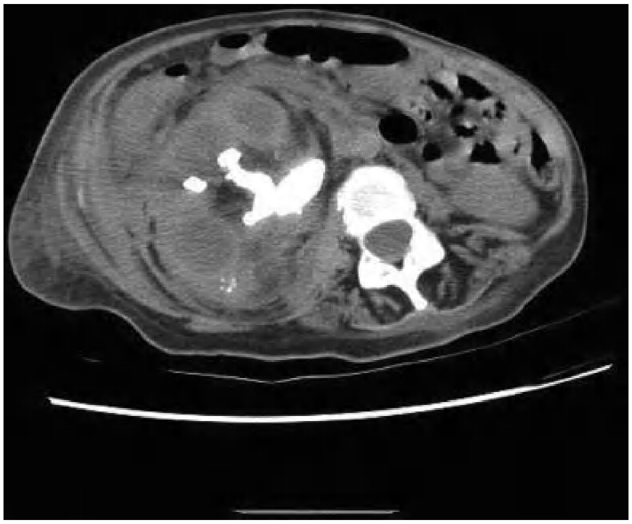

Figure 81.1 Abdominal-pelvic CT scan demonstrating the classic "bear-paw" appearance of a patient with xanthogranulomatous pyelonephritis of the right kidney. Note the presence of renal calcifications along with replacement of the collecting system, with a fatty soft tissue mass representing lipid-laden macrophages. Although perinephric stranding is visible, the intensity of the adhesion formation is not readily apparent as open removal of this kidney required resection of a portion of the liver and mass clamping and oversewing of the hilar structures.

function in the setting of a complete duplication of the collecting system most often is the result of a chronic UPJO or reflux nephropathy [4, 5]. Presenting symptoms include flank pain, recurrent infections, incontinence, or more subtle signs of chronic infection [4]. In such cases, the amount of residual function in the remaining moiety of the affected side justifies whether preservation or removal of that portion of the renal unit should be performed. In cases of reflux or ectopia with obstruction, the associated ureteral segment is also removed as low down as possible to prevent it from serving as a potential reservoir for infection.

Benign cyst disease

The primary indications for decortication of a renal cyst or cysts include pain, hematuria, collecting system obstruction, or associated bowel or respiratory complaints [6–8]. There are four categories of cysts that have been treated laparoscopically with regularity: simple, complex, peripelvic, or cysts associated with ADPKD.

Simple cysts

A possible cause-and-effect relationship between a large simple renal cyst and one of the presenting symptoms noted above is usually established by first performing a percutaneous puncture under ultrasound or computed tomographic (CT) guidance with aspiration of the cyst. If the symptoms improve following the aspiration, then a causal relationship is implied. Unfortunately, puncture and aspiration alone is often inadequate to prevent reaccumulation of the cyst fluid with recurrence of symptoms (Figure 81.2). Instillation of sclerosing agents such as alcohol, providone–iodine, tetracycline, and minocycline increases the overall success rate of percutaneous management to 75–97% [9–13]. Despite the high reported success rate of this minimally invasive procedure, laparoscopic decortication of such cysts is often required as a salvage procedure if symptomatic reaccumulation occurs following percutaneous drainage and sclerosis [7].

Complex renal cysts

Bosniak *et al.* provided diagnostic groupings of cysts based on radiographic findings on enhanced and unenhanced CT scan imaging, which could be used to predict the risk of cystic renal malignancy (Table 81.1) [14]. The incidence of malignancy in Bosniak I lesions is negligible and the high risk of cystic renal cancer in Bosniak IV lesions (90%) requires that they are approached as if they are malignant. The use of laparoscopy for treating Bosniak I and IV lesions therefore is not controversial. There is controversy regarding whether or not laparoscopy should be utilized for the diagnostic evaluation and treatment of symptomatic Bosniak II and III lesions given their risk of malignancy. Obvious concerns exist regarding the possibility of tumor spillage should a lesion prove to be a cystic renal cancer, especially when a transperitoneal approach is utilized. Catastrophic cases of diffuse tumor seeding following transperitoneal laparoscopic decortication have been described [16]. Attempts to define the presence of malignancy via predecortication cyst aspiration cytology have a reported false-negative predictive value of 20% [6]. Traditionally, the safest approach to these lesions has been an open excision, treating the lesions as if they were a malignancy; however, several series have suggested the potential utility of the laparoscopic approach [7, 17].

Peripelvic cysts

Approximately 6% of all simple renal parenchymal cysts can be found immediately adjacent to or abutting the renal pelvis [18]. Although it is not clear what percentage will become symptomatic, cysts located in these areas can result in obstruction of the collecting system with resultant calyceal distention, pain, hematuria, recurrent infections, and stone formation [19–21]. Percutaneous aspiration and marsupialization as well as retrograde ureteroscopic treatment of these cysts have

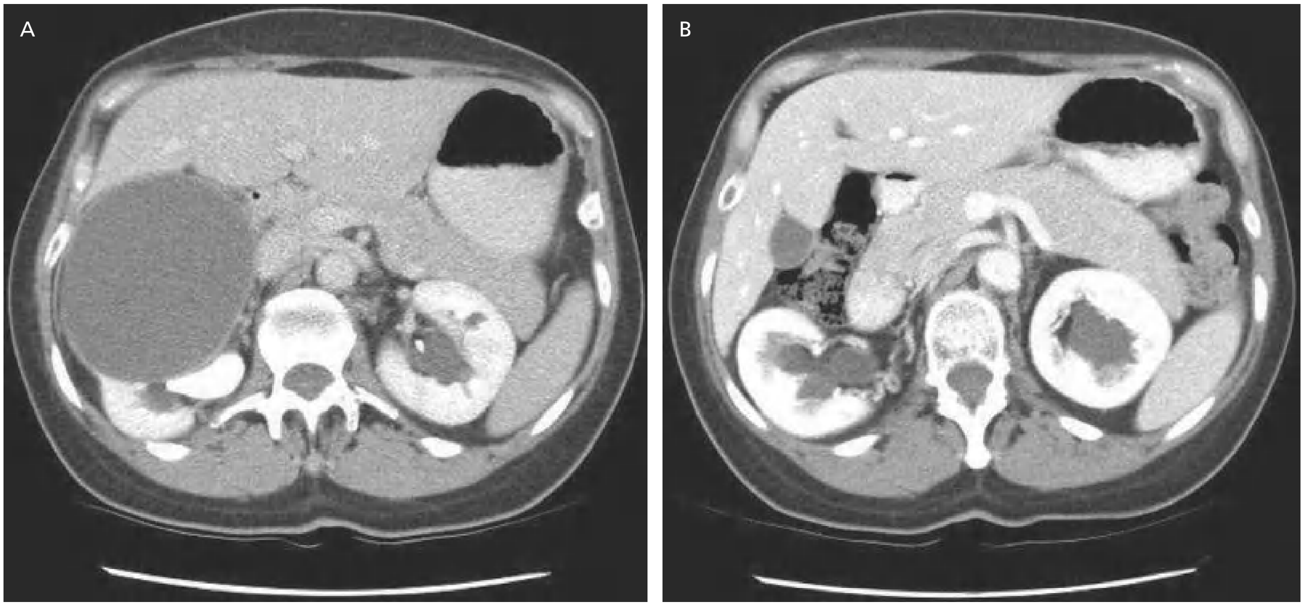

Figure 81.2 Abdominal–pelvic CT scan revealing reaccumulation of a large symptomatic simple cyst of the right kidney, which failed two prior percutaneous aspiration attempts, the last involving sclerosis with alcohol. (A) Note the intimate association and extension of the cyst beneath the inferior edge of the liver. (B) This patient eventually underwent successful laparoscopic cyst decortication.

Table 81.1 Bosniak criteria* [6, 14, 15].

Type	Wall	Septa	Calcification	Enhancement	Malignant Potential
I	Thin	Absent	Absent	Absent	<0.7%
II	Thin	Few	Few	Absent	24%
III	Slightly thickened	Multiple	Multiple	Absent	41%
IV	Thickened	Multiple with nodularity	Extensive with nodularity	Present	90%

*Determined by CT imaging with and without contrast.

been employed with variable success [7, 22, 23]. The use of sclerosing agents in this scenario is risky due to the close proximity of the collecting system and the potential for injury [24, 25]. Due to their location, laparoscopic decortication of these lesions is associated with an increased risk of collecting system injury relative to simple cyst excision [7, 20] and often requires additional operative maneuvers to prevent such occurrences.

Cysts associated with autosomal dominant polycystic kidney disease

Unilateral and bilateral decortications of multiple cysts associated with ADPKD have been shown to improve flank and abdominal pain and, in some cases, associated gastrointestinal and diaphragmatic complaints in these patients [8]. As many as 60% of patients with ADPKD will suffer from chronic flank pain, which is largely thought to be a result of capsular distention providing noxious stimulus of visceral afferent nerves to the kidney [26, 27]. Other potential causes of painful stimulus include episodes of cyst infection, as well as acute hemorrhage [28]. Compression of normal surrounding areas of renal parenchyma has also been hypothesized to create ischemia within the affected kidneys, leading to activation of the renin–angiotensin system with resultant hypertension and progressive decline of renal function over time [28, 29].

Percutaneous aspiration of these cysts often leads to rapid reaccumulation and recurrence of pain. Aggressive open decortications have resulted in more durable pain relief in 80–90% of patients at 1 year; however, progressive recurrence over time has been reported as new cysts form and others enlarge [30, 31]. Ye *et al.* reported initial pain relief in 92% of their patients at 1 year, but this declined to 81% by 5 years [31]. Unfortunately, open decortications were also associated with significant morbidity and even mortalities, with several published series in the late 1950s reporting mortality rates of 11% [32, 33]. A more contemporary series by Fleming *et al.*

described one death among28 patients who underwent open decortications, while 13% suffered prolonged ileus and 10% cardiac dysrhythmias [34]. In 1995, Teichman *et al.* reported the successful use of laparoscopy to perform cyst decortications in six patients with ADPKD [35]. Lee *et al.* more recently reported durable pain relief in ADPKD patients 3 years following laparoscopic decortication, with additional improvements in blood pressure, quality of life, and stabilization of renal function during the study period [8].

Calycealectomy

Calyceal diverticula are transitional cell-lined, dilated chambers that connect with the collecting system via a narrow opening. Their etiology is unclear, but the leading theories include a failure of fusion of one of the branchings of the ampulla of the ureteric bud [36, 37] versus rupture into the collecting system of an adjacent abscess [38]. Approximately 40% have associated calculi [36, 37]. Patients with this condition often present with pain, infections or hematuria [38]. Occasionally, diverticula are asymptomatic and discovered incidentally on imaging procedures performed for other reasons. These may not require surgery, depending upon their size, patient age, comorbidities, and preference. Stone clearance success rates for percutaneous approaches to a stone-bearing diverticulum have been reported to be as high as 70–95%, but 20–33% may have persistence of the diverticulum [39–43]. This technique can be extremely challenging in patients with anteriorly located lesions due to the difficulty of accessing the diverticulum without passing tangentially through a significant portion of the renal parenchyma.

Alternative treatment approaches include shock-wave lithotripsy (SWL) and a retrograde ureteroscopic approach. SWL has a low stone clearance rate of 6–58% [39, 40, 44–47], but a surprisingly high percentage of symptomatic patients (75%) have reported resolution of their symptoms with this technique [45]. If the diverticulum can be accessed from below utilizing a ureteroscope, an alternative approach is to incise or balloon dilate the neck of the diverticulum, and to then attempt to ablate the diverticulum with laser energy or electrocautery. This technique can be cumbersome for large stone burdens and often the neck of the diverticulum cannot be readily identified. In addition, adequate collapse and ablation of the diverticulum often does not occur. Pang *et al.* described a successful stone clearance rate of 66% using this approach [48].

The laparoscopic approach to calyceal diverticula was first described in 1993 [38] and has proven to be ideally suited for anterior- or lateral-based diverticula with associated large stone burden and minimal overlying parenchyma. This approach can also be applied to posterior-based lesions, but is arguably more invasive than the percutaneous approach.

Nephropexy

The condition of nephroptosis (pathologic hypermobility of the kidney) typically presents as intermittent pain in the flank or lower quadrant with standing activities that improves when supine. This condition can also be associated with hematuria, upper or lower tract urinary infections, urinary calculi, or hypertension [49–53]. Classically, it occurs in the right kidney of thin women or patients who have recently experienced a significant weight loss [54], with some series reporting as high as a 10:1 female predominance [55].

Laparoscopic fixation of the kidney to the retroperitoneal fascia (nephropexy) is performed to prevent rotation and/or descent of the kidney to alleviate episodes of pain-inducing obstruction or ischemia. Downward displacement is thought to cause stretching and partial luminal narrowing of the main renal artery, which has been supported by nuclear renal scan and angiographic findings [51, 56, 57]. Previously, nephroptosis was felt to warrant surgery if radiographic descent of the kidney by more than two vertebral spaces (5 cm) on standing relative to supine images was demonstrated [54, 58, 59]. The historic lack of clinical improvement in patients operated on using this diagnostic criterion has lead to a more functional stratification of surgical candidates [54]. Patients with the greatest likelihood of benefiting from a nephropexy have now been defined as symptomatic individuals with documented obstruction [prolonged one-half excretion times ($t_{1/2}$), decreased relative function, and/or renal ischemia (poor 1–2 min perfusion times) on a diuretic renal scan on the affected side that improve on the supine relative to the upright study (Figure 81.3) [54, 59]. Fornara defined the minimum requirements prior to performing a nephropexy as a symptomatic patient with a documented functional difference of at least 10% between the supine and sitting nuclear renal scans [59].

Patient preparation

Patient preparation should include a complete history and physical examination with specific attention to prior transperitoneal or retroperitoneal surgical procedures, episodes of associated peritonitis, locations of abdominal scarring, and other conditions, which could add complexity to a laparoscopic approach [60]. Conditions resulting in hepato- or spleno-megaly such as fatty liver infiltration or portal vein hypertension can also complicate laparoscopic operations on retroperitoneal structures, respectively. Prior lumbar fixations, kyphoscoliosis, or a depressed flattened diaphragm associated

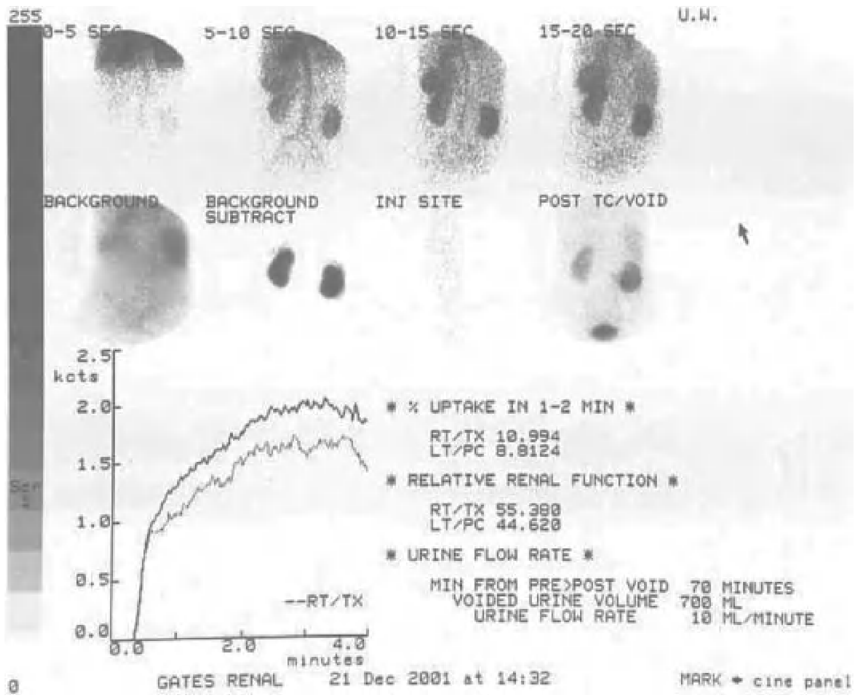

Figure 81.3 *Continued*

with severe cases of chronic obstructive pulmonary disease can also impact the positioning and exposure required for laparoscopic operations. Laparoscopic surgery in the morbidly obese patient, although previously thought to be a relative contraindication [61], has subsequently been shown to be efficacious and to yield results superior to open surgery [62]. This condition does, however, require minor modifications in port placement due to the thickness and mobility of the large abdominal pannus.

Appropriate imaging studies to assist in surgical planning and patient selection should be performed. Our preferred study for patients undergoing laparoscopic simple nephrectomy is a CT scan with and without contrast, which is extremely helpful in outlining the anatomy of the kidney and its surrounding organs. In patients with atherosclerotic disease, careful attention should be given to the artery of the affected renal unit to make sure there is no calcified plaque that can result in clip or staple fracturing and uncontrolled hemorrhage during laparoscopic attempts at securing the vessel [63]. In patients with renal cystic disease, delayed contrast sequences delineating separation between the collecting system and the cyst wall are particularly helpful, especially in cases of ADPKD in whom multiple cysts are decorticated. These delayed images define the relationship of renal pathology to the collecting system and help determine whether or not preoperative ureteral catheter placement is indicated. A plain film prior to and at the end of acquiring the delayed images can also be used to provide coronal imaging of the collecting system when evaluating such nuances as whether or not a stone is located within a diverticulum. Alternative modalities to image patients with a contrast allergy or reduced overall renal function include a noncontrast CT scan or magnetic resonance imaging (MRI) with and without gadolinium administration.

Nuclear renal scan imaging to document poor function in the affected side or moiety prior to nephrectomy or heminephrectomy, respectively, is often performed in addition to the above noted studies. This is a critical imaging study for patients with a duplicated system in whom a potential heminephrectomy is planned. Patients with suspected renin-mediated hypertension can be evaluated using provocative captopril nuclear renal scan imaging or renal vein renin samplings with ultimate "gold standard" confirmation provided by angiography [64]. In patients with radiographically confirmed nephroptosis, the essential diagnostic study is the nuclear renal scan performed in both a supine and sitting position. The initial study often performed in these patients is a stone protocol CT or CT urogram, as the symptoms are difficult to differentiate from an intermittently obstructing calculus or UPJO. The supine and sitting nuclear renal scans need to be performed on two different dates and comparisons made between the 1–2 min perfusion times, relative renal function, and $t_{1/2}$ excretion times. A reduction in the perfusion or prolongation

of the drainage times in the sitting position, in addition to symptomatic changes and demonstrated descent of greater than two vertebral bodies (5 cm) on urogram imaging are diagnostic (Figure 81.3) [54, 59].

Laboratory and additional patient performance assessments are identical to those used for open operations. These should include routine hematologic, chemistry, and coagulation studies, as well as a dipstick and microscopic urine assessment. Patients with atherosclerotic renovascular disease should undergo careful cardiovascular assessment as concomitant carotid and coronary artery disease is often present and may need correction prior to nephrectomy.

We typically perform a type and screen for blood products. Rarely, when more significant bleeding is anticipated, a type and cross or autologous blood donation should be considered. This latter approach may also be applied to all patients early in an individual surgeon's laparoscopic experience. Patients are instructed to avoid the use of Aspirin for 1 week and all nonsteroidal anti-inflammatory medications for 72 h prior to surgery. If the patient is on oral anticoagulant therapy, this should be discontinued at least 5 days prior to surgery if feasible, or the patient converted to short-acting subcutaneous or intravenous agents when the duration off anticoagulation must be minimized.

A mechanical bowel preparation consisting of a clear liquid diet the day prior to surgery and administration of a bottle of magnesium citrate is utilized for all laparoscopic procedures. Cleansing of the bowel is important as it decompresses the large bowel, aiding in visualization and facilitating dissection. In addition, it also limits fecal soiling should a bowel injury occur, and anecdotally appears to speed recovery of bowel function.

Table 81.2 Risk elements of the informed consent for all laparoscopic renal procedures.

Bleeding requiring transfusion
Infection (retroperitoneal or superficial)
Injury to adjacent structures (e.g. bowel, adrenal, spleen, liver, pancreas, etc.)
Renal insufficiency
Thromboembolism
Cardiovascular event
Postoperative bowel obstruction or prolonged ileus
Neuromuscular injury
Hernia formation
Persistent pain
Additional risk elements
Heminephrectomy • Persistent urinary leakage: need for additional drainage procedure (e.g. stent or percutaneous drainage)
Renal cyst ablation • Injury to the collecting system • Persistent urinary leakage: need for additional drainage procedure (e.g. stent or percutaneous drainage) • Cyst recurrence
Calycealectomy • Injury to the collecting system • Persistent urinary leakage: need for additional drainage procedure (e.g. stent or percutaneous drainage) • Stone extrusion • Calyceal or stone recurrence • Persistent pain
Nephropexy • Continued hypermobility

Informed consent

Every procedure that is scheduled to be performed laparoscopically should include the phrase "laparoscopic, possible open" on the surgical posting and consent form. It should also be thoroughly explained to the patient that if it becomes unsafe or deemed impossible to progress laparoscopically, then the procedure will be converted to an open operation. Although a complication such as a bowel injury or uncontrolled hemorrhage can lead to an open conversion of a laparoscopic case, conversion in and of itself should not be viewed by the patient as a complication, but rather a safe alternative for completion of the proposed procedure. Similar to open operations, informed consent for laparoscopic surgical procedures should include a specific discussion of all potential major and minor complications. It should also include an accurate revelation of the individual surgeon's experience with laparoscopy and the particular surgical procedure being performed. If the surgeon will have a proctor or more experienced laparoscopic surgeon assisting them, this should also be clearly discussed, including that individual's qualifications. Utilization of specialized equipment that is new to the operating surgeon, such as robotics, which could significantly alter the flow or outcome of the operation, should also be revealed. Table 81.2 lists the elements that should be included within the informed consent for all laparoscopic renal procedures, including several additions specific for heminephrectomy, renal cyst ablation, calycealectomy, and nephropexy.

Preoperative preparation

On call to the operating room, a broad-spectrum parenteral antibiotic (second-generation cephalosporin) is usually administered. The pneumoperitoneum has been shown to reduce venous velocity and blood return from the lower extremities [65]. To improve the mechan-

ical return of blood from the lower extremities and to stimulate the release of plasminogen activators [66], Ted Hose and sequential compression devices are applied to the lower extremities in all patients undergoing prolonged laparoscopic procedures.

The operating table should be equipped with a kidney rest and push button electric controls allowing for flexion, air-planing, and Trendelenburg positioning. We utilize 3-inch foam padding on the entire surface of the operating table to limit pressure points during the operation. Obese patients with a large abdominal pannus may also require the use of a beanbag to assist in low pressure, contoured securing of all aspects of their excess girth. In cases where the beanbag is utilized, a large gel pad can be placed over its surface and supplemented using additional foam.

Patient positioning: transperitoneal procedures

After the endotracheal tube has been secured, the patient is placed with their down kidney directly over the kidney rest in the flank position, with slight (15º) posterior tilt from the vertical. This degree of angulation improves access to the surface of the abdomen for port placement and lessens medial rotation of the kidney as dissection progresses. Some surgeons prefer vertical flank positioning and then adjust the position by actively air–planing the table at the beginning of the case to assist in port placement, or during the case when medial rotation of the kidney occurs. A posterior gel-pad roll covered by a towel can be positioned lengthwise across the patient's lower back and secured to the table using a double-jointed support arm to provide reliable stabilization of the patient even during full air-planing away from the operating surgeon. The patient's lower leg is flexed and the upper leg is kept straight as ample pillows are placed between the legs to keep them at a comfortable neutral separation without abduction. Pillows should be placed perpendicular to the lower extremities to limit the possibility of the lower leg rolling off the operating table as it is air-planed. Care must be taken to minimize the amount of pillow ends protruding from between the upper thighs as these can inhibit the downward excursion of instrument's inserted through lower quadrant ports. Foam should be utilized to pad the tubing of the sequential compression devices to prevent contact between the body and these firm structures.

We utilize two arm boards placed adjacent to one another on the opposite side of the table from the patient's pathology to support their arms. An axillary roll made from egg-crate foam or gel-pad material is inserted two finger-breadths beneath the axilla to prevent excessive stretch of the brachial plexus while minimizing contact pressure. The kidney rest is elevated slightly and the table is flexed minimally to increase the working space between the lower rib cage and the iliac crest, thus facilitating separation of trocars on the abdomen or flank. Excessive kidney rest elevation and flexion of the table is discouraged as it can actually reduce the working space within the abdomen and may lead to neuromuscular injury to the flank in contact with the operating table [67]. A sufficient number of pillows should be placed between the arms to allow comfortable shoulder width separation. These pillows are oriented in line with the arms and are inserted deep into the axilla of the upper arm; otherwise they will take up too much space along the abdomen and limit upward movements of the laparoscopic instruments.

A strap is placed across the lower legs of the patient in the area of the mid calf and the electrocautery pad is adhered to the upper thigh. Two towels are folded lengthwise and one is placed at the hip just above the cautery pad and extending downward to cover the genitalia, while the other passes from the elbow to across the shoulder of the upper arm. Two to three passes of 3-inch cloth tape are brought from table edge to table edge across the towels, with care taken not to place too much compressive force at the point of body contact. After the tape passes over the shoulder of the upper arm and approaches the elbow, it is split from the far end and wrapped on either side of the tower of pillows on the arm boards (Figure 81.4). This secures the arms, the pillows on which they rest, and the upper torso to the operating table. A foam or gel-pad ring may be required to keep the patient's head in a neutral location after the patient has been positioned. Air-planing and Trendelenburg movements of the table should be tested prior to prepping the abdomen and flank to ensure that all areas of the patient are adequately secured.

When a beanbag is utilized, it is pushed up around the patient's abdomen and back in a cradling fashion with care taken not to elevate the edges so high that they may inhibit downward movements of the laparoscopic instruments. Care must also be exercised to keep the supporting edges broad as suction is being applied to solidify the beanbag; otherwise narrow edges of contact can produce excessive pressure and result in myonecrosis. Two-inch foam strips can be inserted along contact points to provide necessary extra padding.

Bilateral simple nephrectomy is occasionally indicated, with the most common clinical scenario being removal of the native kidneys in kidney transplant recipients due to persistent hypertension, pyelonephritis, vesicoureteral reflux, protein wasting nephropathy, hematuria, or painful cystic disease [68, 69]. In these cases, the operating table is prepared in a similar fashion to that for unilateral cases with the exception that the arm boards are opened on either side at almost 90º to the table. Large foam wedges are placed on each arm board on which the patient's arms rest and are secured

Figure 81.4 Typical patient positioning prior to a right transperitoneal laparoscopic renal procedure. See text for details.

at the forearms. The patient is positioned with their umbilicus at the level of the break in the operating table, the kidney rest is elevated to a neutral position, and the table is flexed slightly. This allows the patient to be fully air-planed to the right or left to elevate the side on which the kidney is being removed, and prevents the need for patient repositioning between nephrectomies [68, 69].

Patient positioning: retroperitoneal procedures

Patient positioning for retroperitoneal procedures is similar to that for transperitoneal operations with several noteworthy exceptions. Since the retroperitoneal space presents a smaller overall working environment and a more limited region of port entry, several maneuvers are critical to optimize both. The patient is placed in a flank position without angulation. This position displaces the lateral peritoneal reflection along with the colon in an anterior direction [70], doubling the undisturbed anteroposterior length of the retroperitoneal space [71]. Chiu *et al.* demonstrated that merely placing a patient in the flank position increased the distance between the quadratus lumborum and the colon by 8.7–27.3 mm on the left and by 4.6–18.1 mm on the right side [72]. The kidney rest is elevated until it is in contact with the flank and more table flexion is utilized than with the transperitoneal approach to enlarge the space between the lower ribs and the iliac wing. This is an important step to enlarge the much more limited surface area for retroperitoneal port insertion. The remainder of the patient padding and positioning is identical to that performed for transperitoneal surgery with the exception that beanbags and posterior gel-pad rolls are not utilized as they can limit the excursion of instruments during retroperitoneal laparoscopic procedures.

Anesthesiology preparations

The anesthesiologists should be encouraged to calculate and replace fluid deficits prior to insufflation of the abdomen to minimize the hemodynamic effects of the pneumoperitoneum that are more pronounced with hypovolemia [73–75]. Nitrous oxide inhalants should be avoided as they can lead to bowel distention, making visualization difficult and increasing the potential for bowel injury [76, 77]. The use of nitrous oxide inhalant during laparoscopy has also been shown to create a gaseous environment in the peritoneum supportive of combustion, which can be potentially catastrophic if electrocautery is being utilized [78]. A urinary drainage (Foley) catheter and oro- or naso-gastric tube are inserted prior to patient positioning to decompress the bladder and stomach, respectively. The Foley catheter should be secured with tape to the lower leg for patients in the flank position. Oliguria during prolonged laparoscopy is common and the anesthesiologist must be well versed on this issue and avoid "chasing the urine output" as this can lead to fluid overload [79–82]. The upper arm should be the site for placement of the blood pressure cuff and parenteral lines for which rapid access may be necessary. A pneumatic patient warming device can be adhesed to the upper extremities and torso or on the lower extremities up to the level of the hips to assist in maintaining patient temperature throughout the case.

Even though the peritoneal surface and bowel is not exposed through a large incision during laparoscopy, heat exchange can still be significant due to the convection flow of the insufflant. Warming of the patient utilizing these devices or insufflant warmers is important to maintain body temperature throughout the case, especially in older patients.

Operative site preparation and draping

The ipsilateral abdomen and flank are shaved from the area of the xiphoid to pubis. A solution of providone–iodine (Betadine) or a similar surface preparation is used to paint the surgical area. The preparation should be wide enough to include the possibility of an open conversion via a flank, subcostal, or midline incision. Special laparoscopic drapes with widened apertures, Velcro straps for cords and tubing, and instrument pockets are commercially available, although a standard paper flank drape can be utilized and the aperture enlarged with scissors to give adequate exposure. Channels can also be created for the light and camera cords, as well as the insufflation tubing, by pulling up redundant drape and clamping it to itself while the cords are brought out through the ends.

Operating room set-up (Figure 81.5)

The operative site and laparoscopic approach determine the variables of the operating room set-up for the

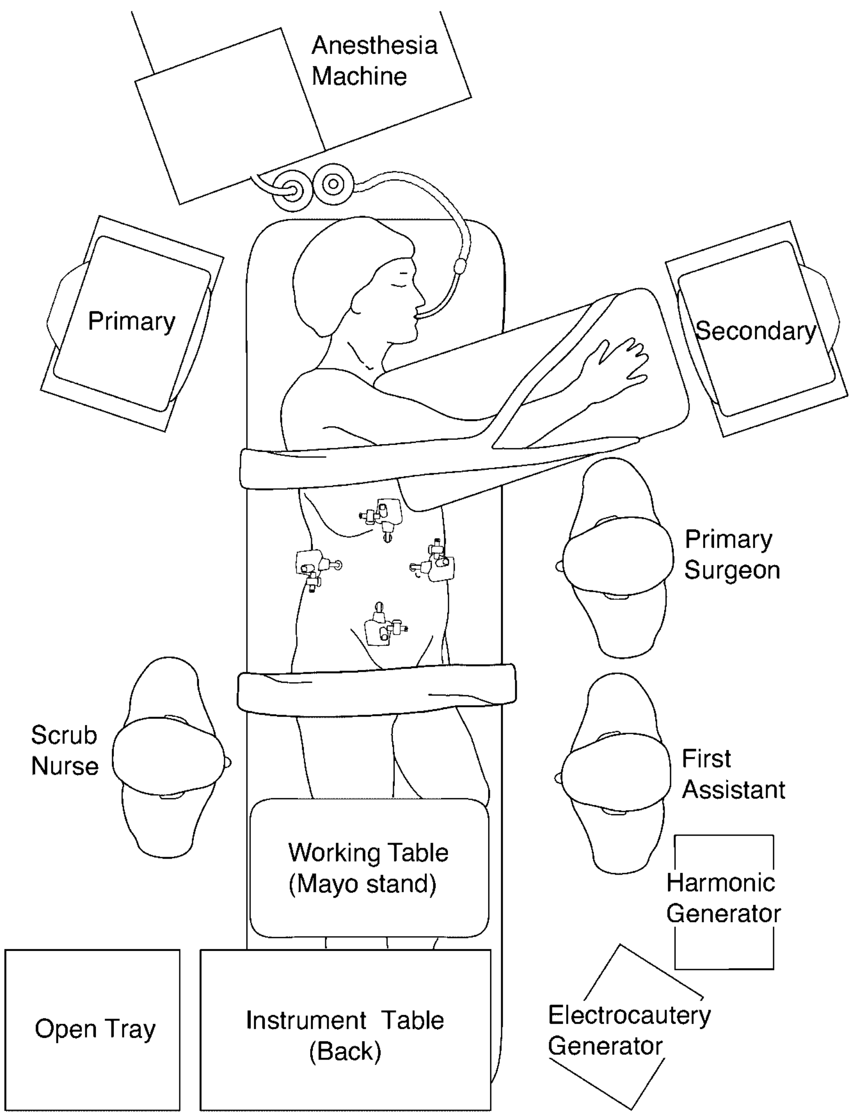

Figure 81.5 Standard operating room set-up for a laparoscopic right-sided transperitoneal renal procedure. See text for details. During retroperitoneal procedures the set-up is essentially a mirror image of the transperitoneal arrangement with the exception of the patient position which remains unchanged. Placement of generators toward the foot of the bed minimizes cord interference with surgeon movements around the operating table.

procedure. The patient is positioned on the operating room table in the flank or semi-flank orientation with their affected side up as outlined above. The surgeon and first assistant stand on the contralateral side of the table to the patient's pathology for transperitoneal procedures and the ipsilateral side for retroperitoneal procedures.

The scrub nurse or technician stands on the opposite side of the table from the primary surgeon, which facilitates passage of equipment directly across the operating table. This arrangement eliminates the need for the operating surgeon to remove their eyes from the primary monitor to reach behind or to their side to receive instruments.

The primary tower containing the insufflator, light source, and camera box is positioned across from the operating surgeon so they can visually inspect the settings as well as the pressure readings throughout the case. The secondary tower is placed on the same side as the primary surgeon for use by the scrub nurse or second assistant. Monitor towers are positioned toward the head of the table and angled back toward the operating surgeon. The height of the monitor must be appropriate for the operating surgeon so upward tilting of the head and subsequent neck fatigue can be avoided. Irrigants are hung on one of the intravenous poles near the head of the patient and the suction canisters are also situated near the anesthetic machine. The scrub nurse places their working table directly over the patient's lower legs. This consists of a Mayo stand on which all frequently used equipment is placed. The back equipment tables are placed end-to-end just lateral to the patient's feet, forming an "L" configuration with the table on the same side as the scrub nurse. The most lateral table contains the open instrumentation.

Simple nephrectomy

The major advantages of the transperitoneal approach to laparoscopic simple nephrectomy over the retroperitoneal approach are a larger working space and anatomy that is familiar to most surgeons. Disadvantages of this approach include the need to dissect and retract the colon, spleen, and pancreas on the left, and the liver and duodenum on the right. There is also an increased risk of visceral complications as a result [63, 83]. The main advantages of the retroperitoneal approach are the limited dissection required of the bowel, avoidance of areas of intraperitoneal adhesion, and rapid posterior access to the main renal artery when performing nephrectomy.

Instrumentation

The instrumentation required is listed in Table 81.3.

Table 81.3 Instrumentation for simple nephrectomy (University of Wisconsin, Madison).

Four nonbladed trocars: two 5 mm and two 10/12 mm (with reducers)
Two 10-mm laparoscopes: one 0° and one 30°
Two 5-mm laparoscopes: one 0° and one 30° (available in the room)
One 14G Veress needle – *transperitoneal*
One trocar-mounted balloon dilation device (Origin Medsystems, Santa Clara, CA, USA) – *retroperitoneal*
One 10/12-mm blunt-tipped cannula (available in the room)
One 10/12-mm visual introducing cannula
One 5-mm curved electrocautery scissors
One 5-mm curved Maryland dissector
One 5-mm curved Harmonic scalpel and generator
One 10-mm locking Babcock
One 5-mm dolphin-nosed grasper
One 10-mm right-angled dissector
One 5-mm toothed locking grasper
One 5-mm electrocautery hook
Two 5-mm laparoscopic needle drivers (available in the room)
One 5-mm diamond flex triangle retractor (Genzyme, Tucker, GA, USA) (available in the room)
One 10-mm PEER retractor (Jarit, Hawthorne, NY, USA)
One Martin arm (available in the room)
One Endo-GIA vascular stapler and two reloads
One 11-mm multiload clip applier
One 5-mm irrigator–aspirator
1 LapSac (Cook Urological, Spencer, IN, USA) (5 x 8 and 8 x 10 inches) (*optional for morcellation of specimens*)
One EndoCatch II bag (Covidien, Mansfield, MA, USA) (*optional for intact specimen removal*)
One grasping needle port closure device
One smoke evacuator valve (Plume-Away: Stryker Endoscopy, San Jose, CA, USA) (*optional*)
One No. 15 blade scalpel and handle
Two fine-toothed pickups
One Tonsil clamp
Two S-retractors
Three 0-Vicryl ties
Four 4-0 absorbable sutures on a cutting needle
¼-inch steri-strips
Benzoin
Open nephrectomy surgical pan

Steps of the procedure: transperitoneal

Step 1: Creation of the pneumoperitoneum and initial entry access

The patient is positioned on the table in a modified flank position, as described above, with the side of the operative pathology placed upwards. A 1-cm incision is made through the skin in the lower quadrant just lateral to the rectus muscle and midway between the umbilicus and the anterior superior iliac crest in nonobese patients. This location may need to be shifted cephalad and lateral in obese patients due to the large abdominal pannus. A small clamp is utilized to spread the underlying subcutaneous tissues down to the level of the fascia. A Veress needle is then inserted perpendicular to the fascial surface. The initial audible "pop" is the puncturing of the fascia, whereas the second represents entry into the peritoneal cavity. This second sound is generated by the snap of the internal obturator of the needle and often can be felt in the introducing hand as well as being heard. The tip of the Veress needle should move freely side-to-side with no perceived resistance, and gentle irrigation and aspiration of saline via a 10-mL syringe should confirm correct positioning of the needle in the peritoneal space. Saline injected into the hub of the Veress needle should flow freely and on removal of the syringe, the column of saline should drain readily into the abdomen under gravity alone ("drop test"). Aspiration of air or enteric contents heralds entry into the bowel by the Veress needle. The abdomen is insufflated to 15 mmHg pressure, elevating the flow rate of CO_2 once it is clear that the initial peritoneal pressures are appropriately low. Initial insufflation pressures should be less than 10 mmHg and higher pressures often indicate entrapment of the needle in the omentum, mesentery, or preperitoneal space.

Vascular and enteric injuries on initial trocar entry of the abdomen have been reported to occur in 0.3% of laparoscopic cases [84]. A review of three series in which 617 access entry injuries occurred demonstrated a 3% death rate following this occurrence, with 59% due to vascular and 41% resulting from bowel injuries [84]. For this reason, we utilize a visual obturator, such as the OptiView (Ethicon Endo-Surgery, Cincinnati, OH, USA) or Visiport (Covidien, Mansfield, MA, USA), to establish initial access. Both allow insertion of the laparoscope into a pistol-shaped introducer placed through the top of a 10/12-mm standard laparoscopic port. The OptiView introducer also comes in a 5-mm size and is shaped like a standard obturator rather than the pistol configuration. Both devices allow visualization of each layer of the abdominal wall as it is traversed. Entry through the peritoneum is heralded by a widening black hole in the center of the visual field through which the device is advanced. During trocar insertion it is important to angle ports toward the area of interest to prevent limitations on excursion and to ensure that the peritoneal and fascial entry points do not line up, therefore limiting the potential for herniation following their removal.

Another option for entry access is utilization of a Hasson cannula via an open technique. This approach usually requires a slightly larger incision to allow adequate exposure of the underlying fascia using the S-retractors. The fascia is incised and a 0 absorbable suture mounted on a semicircular needle, such as a UR-6, is utilized to place a tacking suture through each corner of the fascial incision. The underlying muscular fibers are split using a tapered clamp and the posterior fascial layer is incised, exposing the preperitoneal fat. The thickness of this layer can vary markedly depending upon the habitus of the patient. The preperitoneal fat is spread to expose the underlying peritoneum, which is grasped between two clamps and incised to reveal the peritoneal contents. At this point, we usually replace the tacking sutures to include all of the transected layers. A blunt-tipped open cannula (e.g. Hasson) is then inserted through the peritoneal opening. Variations of this type of trocar are available; however, they usually pass through a cuff that is shaped like an inverted cone, and which is snugged down into the fascial opening and locked in place on the shaft of the trocar. The fascial corner sutures are then wrapped around circular guides on the conical cuff to secure the port in position. Universal or reducers are placed to allow utilization of 5-mm instruments via the 10/12-mm ports.

Step 2: Secondary port placement

After initial access to the peritoneum, a thorough inspection of the abdomen is performed to assess for the presence of adhesions, organomegaly, or altered location of the kidney, which could impact positioning of secondary ports. A skin incision is made for each port that corresponds to the width of the port itself, which can be determined by pressing the mouth of the port into the skin and indenting the epidermis. If the skin incision is too small, it can result in difficult trocar insertion. The increased force required to insert the trocar can ultimately cause rapid uncontrolled entry into the abdomen through a partially collapsed body wall, with resultant injury of the underlying viscera or vasculature. If the skin incision is too large, it can result in leakage of the pneumoperitoneum or inadvertent port dislodgment from the peritoneum. In patients with a nonobese body habitus, a 10/12-mm port is inserted in the periumbilical region. An additional 5-mm trocar is inserted approximately 2 cm below the subcostal margin in the mid-clavicular region. As mentioned above, all ports are shifted lateral and slightly cephalad in markedly obese patients to avoid the abdominal pannus. Placement of

ports too close to the ribs or attached cartilage can inhibit movement of the instruments as they encounter the rib cage. The location of secondary port placement is identical for right- and left-handed surgeons.

Three ports are often adequate for performing left-sided nephrectomies; however, an optional 5-mm port can be placed between the 12th rib and the iliac crest in the posterior axillary line to allow for kidney and ureteral retraction by an assistant if so desired. For right-sided nephrectomies, a similarly located fourth port is often necessary for liver retraction (Figure 81.6). Some surgeons prefer to lower the upper mid-clavicular port on the right and move it more medial, while placing an additional 5-mm port above to be used for liver retraction. This is accomplished by passing a locking instrument through this port, underneath the liver, and grasping the cut edge of the peritoneum on the lateral body wall.

In cases where a bilateral simple nephrectomy is being performed, a total of five trocars are utilized in an "X" configuration [68, 69]. A 10/12-mm port is inserted at the umbilicus, or several centimeters above, with two ports inserted in the right and left mid-clavicular line several centimeters below the costal margin and at the level of the anterior superior iliac spine [68, 69]. These can either all be 10/12-mm ports or, for a right-handed surgeon, the left subcostal and right anterior superior iliac mid-clavicular ports can be replaced by 5-mm trocars. Conversely, for left-hand dominant surgeons, the left anterior superior iliac spine and right subcostal mid-clavicular ports can be replaced with 5-mm ports. Minor upward adjustments to the location of the ipsilateral lower quadrant port may be required when a transplant kidney is present.

The trocars are appropriately positioned within the abdomen by pulling them back until the insufflation port is just within the peritoneal cavity. Ports can be secured to the abdominal wall by placing a 2-0 absorbable or nonabsorbable suture through the skin, tying an air-knot, then wrapping the suture once around the stop-cock and tying it securely. If securing sutures are utilized, the port is rotated so the stop-cock is furthest away from the area of dissection prior to placing the suture. This prevents the stitch from limiting upward movements of the instruments during dissection. Fascial splitting trocars with a grooved shaft are usually held firmly by the split edges of the fascia and are difficult to dislodge, obviating the need for securing sutures.

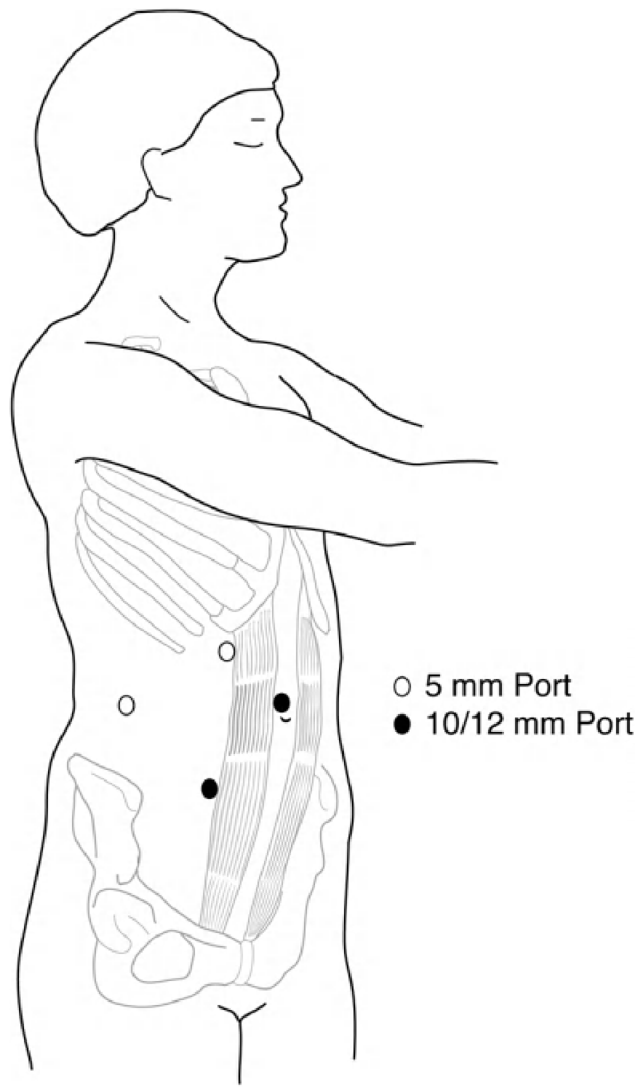

Figure 81.6 Typical laparoscopic port arrangement for a right-sided transperitoneal renal procedure. Trocars are usually inserted near the umbilicus, midway between the iliac crest and umbilicus, just below the costal margin in the mid-clavicular line, and at the anterior axillary line midway between the 12th rib and the iliac crest. Procedure-based determinations of port size will be discussed in each individual operative section. In general, 10/12-mm ports are used at the umbilicus and lower quadrant, whereas 5-mm ports are used at the costal and lateral margins. Modification of port location for obesity involves shifting ports cephalad and lateral to avoid the abdominal pannus.

Step 3: Exposure of the retroperitoneum

Adequate exposure of the retroperitoneum requires mobilization of several key structures. On the left side, upper quadrant adhesions of the omentum or bowel are often encountered and require mobilization to expose the edge of the splenic flexure and descending colon. The laparoscopic lens is usually inserted through the lower quadrant port and the operating surgeon utilizes the Maryland grasper and dissecting instrument via the periumbilical and subcostal port depending upon their dominant hand. The camera can also be inserted via the periumbilical port site and the lower quadrant port used for working instruments, depending upon the area of

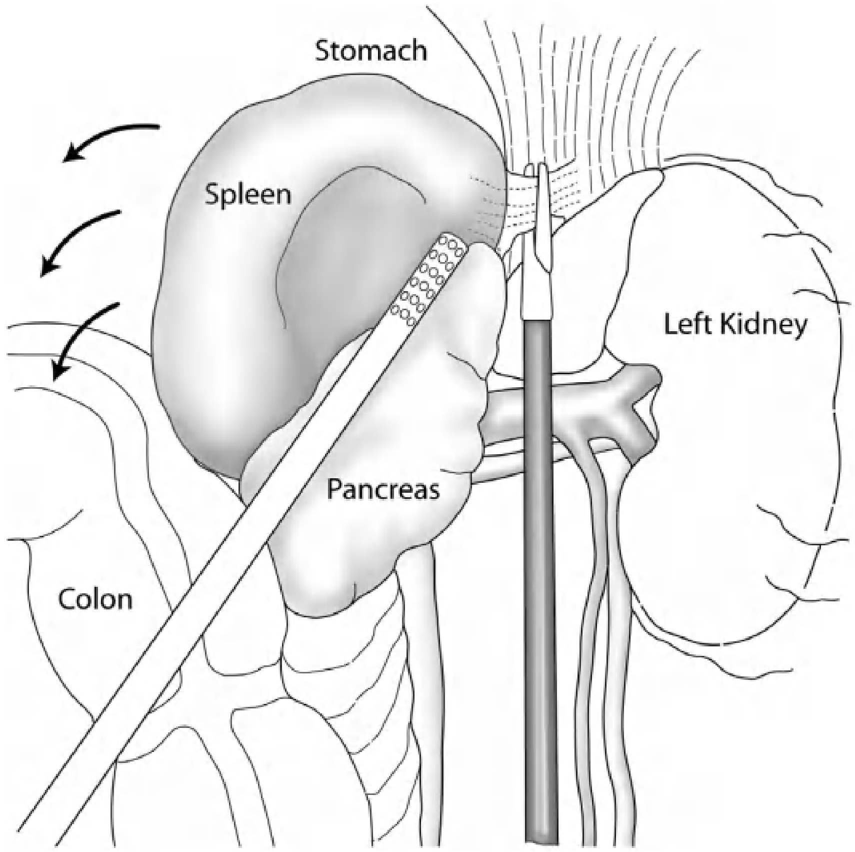

Figure 81.7 Complete exposure of the left retroperitoneum involves complete release of all lateral splenic attachments until the edge of the greater curvature of the stomach is visible. Once released, the weight of the spleen pulls the attached pancreas and bowel medially, protecting these structures while giving complete access to the renal hilum.

the dissection and what port access gives the best visualization. Usually for this part of the dissection, the 0° lens provides a better view of the area of interest, especially as the avascular line of Toldt is incised and mobilization of the colon is carried inferiorly across the pelvic inlet. We typically utilize the Harmonic scalpel for most of the dissection, although the electrocautery shears can also be utilized. The Harmonic scalpel coagulates and divides structures utilizing heat generated from vibrations of the jaws of the instrument at a frequency of 55 500 Hz [85, 86]. This results in intracellular water vaporization, protein denaturation, and release of water vapor instead of smoke. The advantage of this device over electrocautery is its reduced amount of collateral damage, lack of arcing to adjacent structures, reduced impairment of visualization, and its ability to seal and divide vessels as large as 4 mm in diameter [87–89].

In older patients, additional adhesions may be encountered adjacent to the sigmoid colon due to previous bouts of diverticulitis, and care must be exercised not to inadvertently transect enlarged diverticula in this region. The dissection should be carried cephalad to release all lateral attachments of the spleen while gently lifting it up using the shaft of an instrument inserted through the upper port. Splenic mobilization should continue until the greater curvature of the stomach is visualized (Figure 81.7). This is a critical step on the left side because the spleen will act as a dead weight to draw the pancreas and colon medial, thus giving better exposure of the kidney and preventing these structures from being injured. The plane between Gerota's fascia and the posterior aspect of the colonic mesentery is often easily discernable and usually can be teased apart by a combination of blunt and cautery dissection. The vessels within the mesenteric fat and the smoother surface of the thin layer of Gerota's fascia overlying the retroperitoneal fat often provide additional clues to differentiating between these two layers. Separation along this plane should continue down across the pelvic inlet and the colon folded back on its mesentery until the pulsation of the aorta is visualized.

On the right side, the line of Toldt is similarly incised down around the cecum extending into the pelvis. The upper mid-clavicular and periumbilical ports are usually utilized for the dissection. The liver is mobilized by transecting the triangular ligament laterally and the coronary ligament below its lower edge. A 5-mm Diamond Flex Triangle retractor (Genzyme, Tucker, GA,

USA) can be utilized for broad-based secure elevation of the liver via the lateral port between the 12th rib and iliac crest. Once positioned beneath the liver, the retractor is secured to the operating table using a robotic (e.g. Martin) arm. The right colon and its mesentery are separated from Gerota's fascia as described for the left-sided dissection. As the colon is rolled medially, the duodenum can be visualized in the upper portion of the retroperitoneum and is kocherized to reveal the underlying inferior vena cava (IVC). It is important to realize that, with rare exceptions, the duodenum overlies the vena cava and requires medial mobilization to adequately expose the right renal vein and upper IVC.

Step 4: Securing the ureter

The remaining steps of the operation are typically performed using a 30º laparoscopic lens inserted via the lower quadrant port. The surgeon operates through the subcostal and periumbilical ports with the dominant hand usually controlling the dissecting instruments. The ureter is identified as one of two tubular structures running in a craniocaudal direction in the retroperitoneum. It usually lies deep and lateral to the similar appearing blue-tinged gonadal vein. After adequate mobilization of the sigmoid colon, the ureter can almost always be visualized after it crosses the iliac vessels and heads into the pelvis. If it cannot be directly visualized, sometimes it provides enough tactile sensation as a firm "band-like" structure in the retroperitoneum to allow localization when a laparoscopic instrument is drawn across it from lateral to medial. Gentle squeezing of a nonpulsatile tubular structure that produces a peristaltic wave confirms that the observed structure is the ureter.

The upward-directed tips of the Maryland dissector are used to elevate the ureter either together or separate from the gonadal vein. On the right side it is preferable to release the gonadal vein medially, so it is not placed on any significant traction during the dissection as this can result in aneurysmal dilation or rupture of its very weak entry point into the IVC. The periureteral tissues can be separated using gentle downward blunt dissection, together with Harmonic coagulation and division whenever more substantial tissue bands are encountered as these often contain ureteral feeding vessels. Complete creation of a window beneath the ureter is facilitated by first opening Gerota's fascia lateral over the psoas musculature. The dissection is carried up along the top of the psoas to the region of the lower pole of the kidney. At this point, we typically secure and divide the ureter by placing a total of three 11-mm clips and cutting between the first and second clips. If easy separation of the gonadal vein and ureter cannot be performed, we divide the ureter, gonadal vein, and periureteral tissues together, utilizing the Endo-GIA stapler with a vascular (2.5 mm) load.

Step 5: Dissection and securing of the hilum

Differences in the vascular anatomy between the right and left kidney require slight alterations in hilar dissection techniques between the two sides. On the left side, the gonadal vein drains into the left renal vein and therefore can be utilized as a convenient method for identifying the surface of this structure. The tissue overlying the anterior surface of the gonadal vein is divided starting at the most proximal part of the vein that is visible. The Harmonic scalpel is ideal for performing this part of the operation as there can be small branches, which enter the gonadal vein medially and can cause troublesome bleeding if the tissues are merely transected. The gonadal vein is traced cephalad until the surface of the main renal vein is exposed on the left.

On the right side, the gonadal vein drains into the vena cava and can be used in a similar fashion to identify the caval surface, although extreme care should be taken in dissecting around this structure due to the fragility of its entry point into the IVC and risk of avulsion. It is important to separate the gonadal vein from the ureter so it can be swept medially, or to clip and divide it several centimeters distal to the IVC to prevent traction at its entry point. Often the surface of the IVC is readily visible after medial mobilization of the duodenum and tracing the gonadal vein is unnecessary. The medial surface of the vena cava should then be exposed and followed cephalad to the entry point of the right renal vein, which often lies higher than anticipated relative to the predicted mid region of the kidney. Once the renal vein is identified, the correct dissection plane directly on the surface of the vein is established by incising the overlying adventitial tissue. The surrounding fibrofatty and lymphatic tissue is grasped and the vein is rolled away and peeled out of the confines of this tissue on both its superior and inferior surfaces using blunt dissection.

On the left side, the adrenal vein branch is identified entering the cephalad surface of the main renal vein and is usually slightly medial to the entry site of the gonadal vein below, although the two sites can emerge from the same location. During this part of the dissection, the assistant can elevate the kidney by grasping the ureter from the lateral-most port if one has been placed. Alternatively, a 2-0 nylon mounted on a Keith needle can be passed through the abdominal wall, followed by the wall of the ureter or periureteral tissues, and back out through the abdominal wall. The suture is then secured with a clamp (Figure 81.8). This can be elevated and lowered as desired to place the hilum on stretch, prevents the need for a lateral trocar on the left, and on

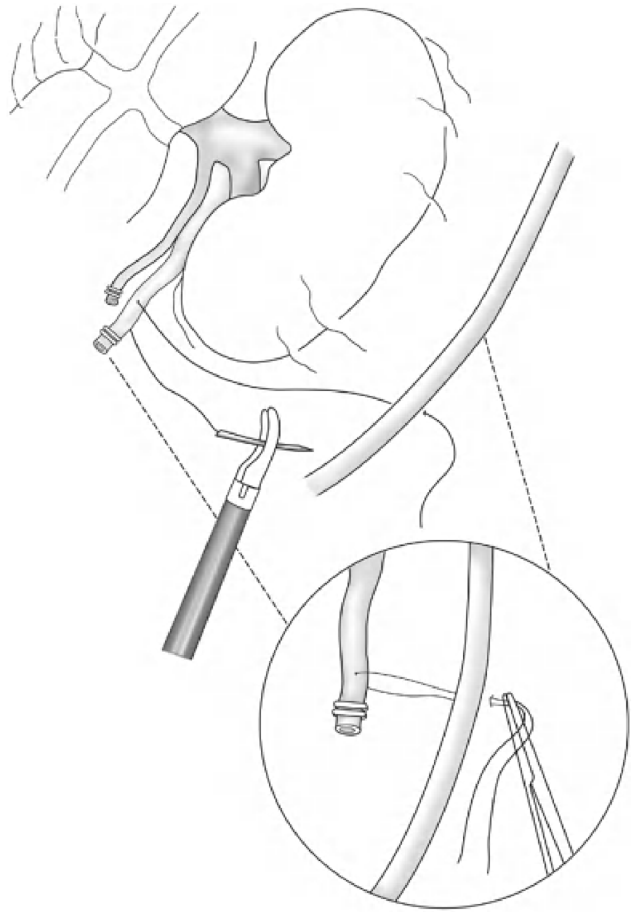

Figure 81.8 A 2-0 nylon mounted on a Keith needle can be utilized to provide variable amounts of kidney elevation without the need of an assistant's instrument. For the left side, this can alleviate the need for a lateral-most trocar. The needle is passed through the abdominal wall, then through the upper ureter or pelvis, and back out of the abdominal wall. The needle is removed and tension on the suture can be altered to provide varying amounts of internal retraction as needed. (Insert) A clamp is placed on the suture ends at skin level to maintain the desired position.

the right enables continuous maintenance of liver retraction through the lateral trocar during this part of the dissection.

Completion of the hilar dissection can be performed utilizing either an anteroinferior or a posterior approach to the renal artery:

Anteroinferior approach

This approach usually requires clipping and dividing of the gonadal, adrenal, and underlying ascending lumbar vein branches on the left side. The ascending lumbar vein branch invariably crosses over the base of the renal artery and tethers the renal vein, making anterior exposure to the artery difficult. A total of four clips are placed on large branch veins and Endoshears are used to divide between the third and fourth clips. The Harmonic shears can be utilized to divide vein branches up to 4 mm in size by placing the Harmonic generator at a variable setting of 2. It is then used to create a coagulative seal at two widely spaced spots on the vessel, followed by coagulation and transection between the sealed areas. Care should be utilized not to inadvertently contact the main renal vein with any portion of the Harmonic shears as this can lead to a thermal puncture.

The adrenal vein branch is similarly isolated and the overlying lymphatic and fibrofatty tissues dissected until a right-angled dissector can be passed behind it. If the degree of fibrosis around the kidney allows it, we release the edge of the adrenal gland from the medial aspect of the kidney prior to clipping and dividing the adrenal vein branch. The Harmonic shears are the ideal instrument for performing this part of the procedure as they efficiently seal the large number of small arteries that feed the adrenal gland. The jaws of the Harmonic are opened and the lower noninsulated jaw is pushed several millimeters into the tissues with the backside of the instrument flush on the adrenal gland to prevent injury to an early arterial branch or late upper pole vein confluence of the renal vasculature. The jaws are then closed and activated. If bleeding occurs from a partially transected vessel, then advancement of the jaws across the area of bleeding is performed to complete the coagulation and transection. The adrenal gland does not swell and ooze as much utilizing this approach as it does if the main adrenal vein branch is transected prior to dividing the medial arterial twigs. If the medial adrenal plane is difficult to establish, the adrenal vein branch is clipped and transected, and dissection of the main renal vasculature is continued. The adrenal vein branch can also be spared in cases where there is adequate vein length between the gonadal and adrenal vein branch entry points to allow either straight or angled application of the Endo-GIA stapler across the main renal vein (Figure 81.9).

As the assistant lifts the ureter and lower pole lateral to place the hilar vessels on stretch, the packet of lymphatic tissue between the artery and vein can be grasped and the artery and vein peeled away. The tissue between the vessels can then be divided by sequential transection using the Harmonic dissector until a right-angled clamp can be readily passed behind the artery and vein. Spreading of the right-angled dissector should confirm the presence of approximately 2–2.5 cm of space to allow easy passage of the Endo-GIA stapler. The hilum is placed on stretch by inserting the irrigator–aspirator through the upper port and placing it between the artery and vein and then lifting (Figure 81.10).

We prefer to use the 2.5-mm vascular Endo-GIA stapler to secure and divide the artery and vein.

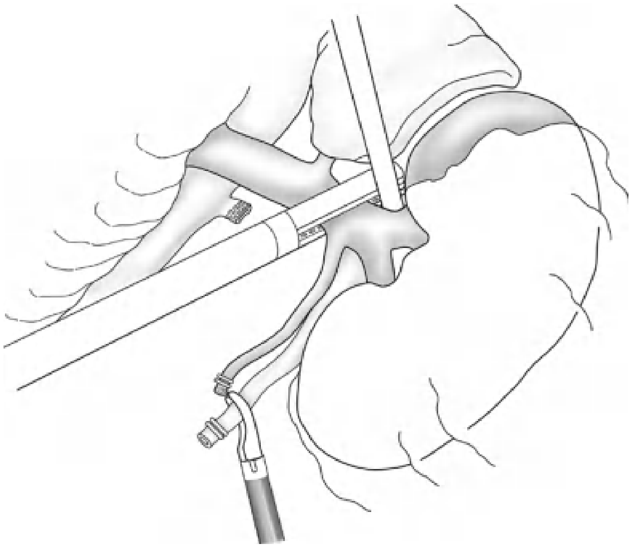

Figure 81.9 Once the renal artery has been secured and transected via a posterior approach, it is often easiest to approach the renal vein anteriorly. The kidney is flipped back into its lateral position and is slightly elevated by the assistant's grasper or a transabdominal nylon suture. The adrenal vein branch can usually be left intact with this approach. To gain extra venous length lateral to the adrenal vein branch to allow application of the endovascular stapler, a blunt instrument such as the irrigator–aspirator can be inserted posterior to the kidney along its medial edge for elevation and lateral retraction, maximizing the space between the edge of the adrenal gland and the upper pole of the kidney.

However, the interlocking Weck clips (Weck Closure Systems, Research Triangle Park, NC, USA) also provide a safe means of controlling the arterial and, in some cases, the venous stump. Three Weck clips are placed on the artery and Endoshear division is performed, leaving two clips on the stay side. Five clips are placed on the vein, dividing between clips so three remain on the stay side. Caution should also be exercised when applying Weck clips to make certain the toe and recipient latch of the clip are entirely across the vessel being secured; otherwise the clip can puncture through the wall of the vessel and result in significant hemorrhage. All surrounding lymphatic tissue should also be released to prevent it from becoming entrapped in the locking mechanism of the clip, resulting in incomplete closure and possible delayed opening.

The device used to secure the hilar vessels can be introduced via the periumbilical or lower quadrant port, depending upon which provides the best angle of approach to the hilum. This is especially important if the stapler does not articulate. The narrow jaw of the stapler is slid between the artery and vein, and the stapler advanced until the black marking line on the lower jaw passes the far wall of the artery and the device is clamped. Visualization of what is contained within the jaws of the instrument prior to firing the staple line and transecting the tissue is facilitated by rotating the device clockwise and then counter-clockwise [90]. This careful inspection is necessary as 50% of the 1.7% of vascular

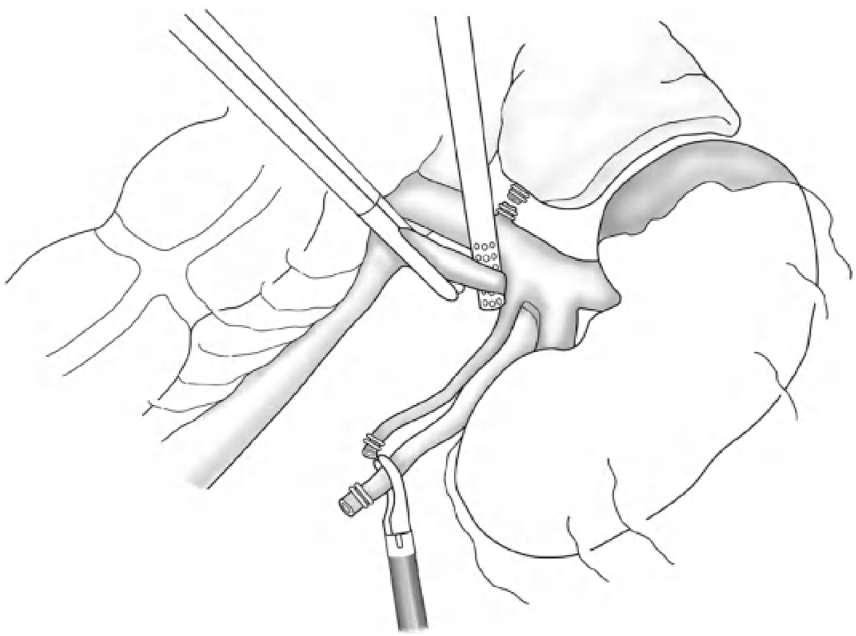

Figure 81.10 The anteroinferior approach to the renal artery usually requires division of the adrenal vein branch to provide enough mobilization of the vein to enable cephalad retraction. Simultaneous elevation of the kidney and separation of the artery and vein can be achieved by insertion of the tip of the irrigator–aspirator between these two structures. The narrow jaw of the endovascular stapler can then be passed between the artery and vein, while the wider jaw passes inferior to the artery. Once the jaws of the stapler are closed, the instrument can be roticulated to confirm correct positioning.

Endo-GIA misfirings are due to application on previously placed clips [90].

Once the artery is transected, the vein should appear collapsed and the specimen should lose some of its turgor. If these changes are not observed, then a careful inspection for accessory arteries should be performed. Once the surgeon is confident that the kidney no longer has arterial flow, the vascular Endo-GIA stapler is passed across the vein in an area free of clips, as well as the distal arterial staple line, and the vein is secured and divided.

The anteroinferior approach to the right kidney is identical to what is performed on the left with the exception that no branches usually enter the main renal vein, and if they do, they are usually small secondary vessels that can be divided using the Harmonic scalpel. Although it is short, the right renal vein will usually accommodate the stapler. Another advantage on the right side is that many times the right renal artery lies slightly below the main renal vein thus facilitating its identification and isolation.

Posterior approach

The posterior approach, or posterior renal artery control [91], is usually employed any time the artery cannot be readily controlled from the anteroinferior exposure. The advantage of this maneuver on the left side is that it gives excellent access to the entire length of the artery, often obviating the need to transect the lumbar vein as the artery can be secured and transected distally. If the renal vein segment is lengthy between the gonadal vein branch and the entry point into the hilum, it may be possible to leave all branches of the left renal vein intact with this approach.

During this maneuver, Gerota's fascia and fat are divided over the lateral aspect of the kidney using the Harmonic shears as outlined in Step 6 below. The fat is released laterally as the kidney is rolled medially. A blunt instrument such as the suction–irrigator should be utilized to roll the kidney, preventing parenchymal injury. If this plane cannot be established due to fibrosis, then a dissection and release lateral to Gerota's fascia, as done during a radical nephrectomy, can be performed. Division of the more cephalad attachments is also required to allow the kidney to be completely flipped medially. Careful inspection of the hilar area usually reveals pulsations of the artery. The fibrofatty tissues overlying the artery are grasped and divided until the smooth surface of the arterial wall is visible. The artery is then shelled out of the surrounding lymphatic tissue until a right-angled dissector can be completely passed behind it and spread to allow placement of the vascular Endo-GIA stapler or Weck clips. The assistant can utilize the lateral port, if present, to push the kidney medial and to keep the hilum on stretch during dissection and securing of the artery.

Once the artery is divided, the kidney is flipped lateral and the assistant elevates the ureter and lower pole of the kidney via the lateral port, or the primary surgeon elevates it via the upper port, to visualize the vein. The upper edge and posterior surface of the main renal vein are dissected free of all surrounding tissue lateral to the gonadal vein branch until a right-angled dissector can be easily passed and spread behind it. This enables clear placement of the Endo-GIA around the vein, which is then transected. The posterior approach to the hilar dissection on the right side is identical to that described on the left.

In cases of severe perivascular fibrosis, several groups have described early *en bloc* ligation and division of the renal artery and vein [92, 93]. The hilum must be skeletonized as much as possible to allow application of the stapler. Shekarriz *et al.* described use of the wider (3.5 mm) clips to accommodate the increased bulk of the dual vasculature and associated hilar tissue [92]. In their series, five patients were managed in this fashion without a significant bleeding event or delayed fistula formation after 2 years of follow-up. Rapp *et al.* described similar *en bloc* division of the hilar vasculature using a laparoscopic Endo-GIA stapler application during laparoscopic nephrectomy or nephroureterectomy in 26 patients, none of whom suffered a fistula or catastrophic bleeding event on mean follow-up of 26 months [93]. We do not generally advocate this approach as other authors have demonstrated the possibility of acute bleeding or delayed arteriovenous fistula formation in a pig model [94].

Step 6: Release of the lateral and cephalad renal attachments

Once the hilum has been secured, the lateral attachments are released if they have not already been freed using the Harmonic scalpel. If the amount of scarring around the kidney does not allow easy dissection between Gerota's fat pad and the renal capsule, the dissection should proceed outside Gerota's fascia similar to a radical nephrectomy. An alternative is to perform a subcapsular dissection for cases of severe perinephric fibrosis [95]. In this technique the parenchyma and collecting system are "shelled out" of the capsule, leaving the posterolateral capsule and all of the surrounding tissue behind. The lateral attachments are released by incising Gerota's fascia parallel to the lateral border of the kidney. The lower pole is then elevated by the surgeon grasping the ureter, or bluntly retracting it, while teasing and transecting tissue from superficial to deep layers. The kidney is rolled medially and the dissection is carried out cephalad. Often complete release

of the cephalad attachments requires flipping the kidney to approach it from the anterior and then posterior side. If poor planes exist, an alternative to separation of the cephalad attachments is to create windows in the tissue, separating it into smaller bundles that can be secured using the Endo-GIA stapler. Once it is completely released, the kidney is placed adjacent to the spleen on the left or on the surface of the liver on the right to facilitate entrapment of the specimen.

Step 7: Entrapment with morcellation or intact removal of the specimen

Entrapment with morcellation

It is our preference to morcellate noninfected specimens for which we typically use an EndoCatch II (15 mm) bag (Covidien); however, the smaller EndoCatch I (10 mm) bag (Covidien) can also be utilized. It is easier to operate and is safe for benign specimens. Both bags are mounted on a metal ring, which is delivered by advancing an inner core handle to spring the bag open. An encircling drawstring is then pulled to close the bag on the specimen, tearing it away from the metal ring. The inner core handle is then pulled back, withdrawing the metal ring, and the device is removed, leaving the bagged specimen and drawstring in the peritoneum or retroperitoneum.

Alternatively, a LapSac (Cook Urological, Spencer, IN, USA) can be utilized. The LapSac is made of nylon with a polyurethane inner coating and has been shown to be impermeable to substances such as indigo carmine and albumin, which are smaller than uropathogenic bacteria, providing the option for morcellating specimens that have a strong likelihood of containing infectious organisms [96]. The LapSac should also be utilized if a high-speed tissue morcellator is utilized as it has the highest resistance to mechanical perforation [97]. The 8 x 10-inch LapSac will hold most specimens with the exception of very large (>1000 g kidneys. Noninfected specimens can be morcellated in either a nonpermeable LapSac or an EndoCatch II bag, although the latter is less resistant to perforation [97].

The EndoCatch II bag is inserted through the lower quadrant port site after removing the port as it is too large to fit through the lumen of a 10/12-mm trocar. The assistant opens the EndoCatch II bag with the mouth of the ring just below the kidney, as the surgeon grasps the ureter with the dominant hand and slides the lower pole of the kidney off the spleen or liver into the bag. The upper pole is guided into the bag using a dissector inserted through the subcostal port. Once the kidney and attached tissues are completely within the bag, the drawstring is then pulled to close the device, which is then withdrawn as described above. As already mentioned, care must be taken when morcellating specimens in the EndoCatch bag as its resistance to perforation is minimal compared to the LapSac [97]. An empty sponge stick is an excellent instrument for fracturing and removing the kidney while the bag is kept under careful inspection from the peritoneal side. The entrapment sac is elevated through the trocar site and its edges rolled back to feed it out as the specimen dissipates. Eventually the entire bag can be removed and the port site is then irrigated and the trocar reinserted using the appropriate obturator.

The LapSac is also too large to pass through a standard 10/12-mm trocar, so the periumbilical port is removed, and the sac is rolled and stuffed manually or with the aid of an introducer deeply into the abdomen. The port is reintroduced and the sac is unwound within the peritoneal cavity. A standard 0.035-inch glidewire can be passed twice through the drawstring holes of the LapSac, skipping every other hole on the first pass and traversing the skipped holes on the second pass. The mouth of the sack is positioned below the spleen or liver, depending upon the side of the nephrectomy. The bottom of the bag is pulled down onto the psoas and the inferior lip of the sac is slightly elevated as the laparoscopic lens is inserted into the bag and moved in circular motions to open the sac. The posterior tab of the sac is held up with a grasper inserted through the upper port, and the anterior tab of the sac is held open via the lower quadrant port with the laparoscopic lens inserted via the periumbilical port. The lower pole of the kidney is then slid into the sac with the aid of a grasper inserted via the lateral-most port. Once the kidney is pushed deeply into the sac, the drawstring is brought out via the lower quadrant port site and the bag is elevated through the skin. If a potentially infected specimen is morcellated, antibiotic-soaked towels are placed around the port site as the morcellation process proceeds, and gloves and gowns should be changed following the morcellation and the port site irrigated with antibiotic solution. Dirty instruments used in the morcellation process should be removed from the surgical field. Large ADPKD kidneys require fluid decompression prior to extraction by either morcellation or intact specimen removal.

Entrapment with intact removal

In some cases, such as an infected kidney bearing a large staghorn calculus, it may be desirable to remove the specimen intact. Clayman *et al.* demonstrated that removal of the specimen via a lower quadrant incision connecting the port sites resulted in an increased incidence of hernia formation [98]. We prefer to use a periumbilical or Pfannenstiel incision for intact extractions. In this technique, a standard incision is made in one of these two locations down to, but not through, the peri-

toneum. A purse-string 2-0 Vicryl suture is placed in the exposed center of the peritoneum or around the periumbilical port site if utilized. The peritoneum is then incised with the cautery, or the port removed, and a large EndoCatch II bag is inserted through the peritoneal opening. The purse-string suture is tied down around the sleeve of the EndoCatch device allowing re-establishment of the pneumoperitoneum. The kidney is then captured in the EndoCatch as previously described, and the peritoneal incision is widened and the specimen removed. Alternatively, the surgeon's arm can be inserted into the incision until the forearm prevents loss of the pneumoperitoneum, and the kidney can be grasped with the introduced hand and removed [99]. In this method the peritoneal incision should be just large enough to allow introduction of the forearm. After removal of the specimen, the peritoneum is closed using a running 2-0 Vicryl, and a moistened laparotomy pad is placed in the incision.

Step 8: Exiting the abdomen and port closure

Final inspection of all areas of dissection is performed under low insufflation pressures of 5 mmHg to look for venous hemorrhage that might otherwise be compressed by the pneumoperitoneum. Careful inspection of the hilar vessel stumps is also performed. The Harmonic shears can be utilized for obtaining hemostasis of localized areas of bleeding away from the main hilar vascular stumps. We place a half-sheet of oxidized regenerated cellulose (Surgicel; Johnson & Johnson, Arlington, TX, USA) at the area of the transected vessels, along the margin of the adrenal gland, and any other areas where persistent venous oozing is noted. After hemostasis is deemed adequate, the pressure of the pneumoperitoneum is increased to 15 mmHg. It is not necessary to reperitonealize the colon as this occurs rapidly with or without suture placement.

We place a 0-Vicryl closure suture at each of the 10/12-mm port sites with the aid of a fascial closure device, such as the Carter–Thomason (Inlet Medical, Trumball, CT, USA) [100], which has been shown to be one of the more efficient means of closing the fascia in animal and clinical studies [101, 102]. The other advantage of this type of device is that it allows full-thickness closure of the port site, including both fascia and peritoneum, which is important as subfascial herniations have been reported following laparoscopy [103, 104]. The Carter–Thomason can be utilized in one of several ways, the easiest of which is to grasp the Vicryl closure stitch 1–2 cm back from its end and to pass a full-thickness simple suture through the center of the cut fascial edges on either side of the port, leaving the port in place. A grasper is utilized by the assistant via one of the other ports to hold the end of the suture, and the device is then removed. The Carter–Thomason grasping needle is reinserted through the other side of the fascia, the suture is transferred to the jaws of the device within the abdomen, and it is withdrawn and tagged with a clamp. A conical guide with holes for passage of the closure needle through the fascia is also available to facilitate use of this device, but it can only be utilized after removal of the port, which then needs to be reinserted after placement of the stitch. The final alternative is to remove the port and to use the index finger of the non-dominant hand inserted into the fascial defect to guide insertion of the needle, which is pinched between the thumb and the inserted index finger while maintaining the pneumoperitoneum. An advantage to utilizing the finger is the ability to feel the edges of the fascial opening, which are not always parallel to the skin incision when fascial splitting or nonlinear cutting trocars are utilized. The instrument companies and some surgeons advocate that it is not necessary to close the fascia for fascial splitting trocars [105]; however, we described a case of port site herniation via such a port site following a laparoscopic donor nephrectomy [106]. As a result we now place a closure suture at nearly all 10/12-mm fascial defects. The 5-mm port is removed first under vision, so a suture can be placed using the other ports if bleeding is observed.

The last port closed is the lower quadrant port through which the pneumoperitoneum is evacuated to prevent CO_2 irritation of the diaphragm. The patient is placed in the slight Trendelenburg position and is given several extended large volume respirations to evacuate as much of the retained insufflant as possible. Once complete evacuation of the CO_2 has been performed, the closure suture is elevated and the port is pulled out of the abdomen while the laparoscope is left within the peritoneum. The laparoscope is then slowly withdrawn in a perpendicular axis to the patient, making sure bowel and omentum drop away as the laparoscope passes out through the fascial opening. The final fascial suture is then tied and the incisions are irrigated with antibiotic solution. If a Pfannenstiel incision was created, the fascia is closed using a #1 Polydioxanone suture and the subcutaneous tissues reapproximated with several interrupted 3-0 absorbable sutures. Each incision site is injected with 0.25% bupivicaine (Marcaine) and a subcuticular closure is performed using 4-0 absorbable suture. Steri-strips are placed with the aid of benzoin followed by a band-aid at each of the port sites.

Steps of the procedure: retroperitoneal

Step 1: Initial entry access and creation of the pneumo-retroperitoneum

McDougall *et al.* describe the use of a Veress needle inserted into the retroperitoneum at Petit's triangle

(inferior lumbar triangle) just above the iliac crest in the posterior axillary line [107]. A CO_2 pneumo-retroperitoneum is created to 15 mmHg pressure and the initial 10/12-mm port is inserted at this site. More commonly, an open retroperitoneal access is utilized by first making a 1.5–2-cm incision just below the tip of the 12th rib, then spreading the underlying fat down to the lumbodorsal fascia using two S-retractors. The lumbodorsal fascia is then punctured using a Tonsil clamp and the underlying muscle fibers split until the fat of the retroperitoneal space can be visualized. A 0-Vicryl suture mounted on a semi-circular (UR-6) needle can be inserted through each fascial edge to assist in securing the Hasson-type cannula. The surgeon inserts an index finger into the retroperitoneum, sweeping away the underlying fat until the smooth surfaces of the psoas and quadratus lumborum musculature are palpated, and the edge of the peritoneal envelope is swept as far medially as the length of the inserted finger will allow. At this point many authors favor use of a trocar-mounted balloon dissection device (e.g. Origin Medsystems, Santa Clara, CA, USA) to facilitate creation of the retroperitoneal space [108]. This device consists of a trocar with an attached lucent balloon that is positioned between the posterior surface of Gerota's fascia and the psoas muscle, and is then inflated with air while performing direct vision monitoring via a laparoscope inserted through its lumen (Figure 81.11). The amount of instilled air depends on the size of the patient, with 400–600 mL instilled in pediatric and 800–1000 mL in adult patients [70]. Positioning of the balloon outside of Gerota's fascia has been shown to give rapid and reliable access to the posterior aspect of the renal hilum.

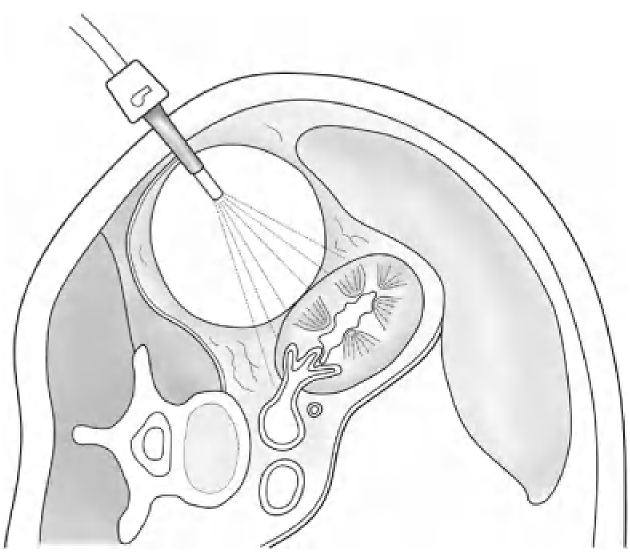

Figure 81.11 Several trocar-mounted retroperitoneal balloon dilators are commercially available through which the laparoscope can be inserted. These dilators allow confirmation of correct balloon positioning and direct inspection of the retroperitoneal contents as the dilation is being performed.

Alternative methods for creating the retroperitoneal space include insertion of a red rubber catheter on which the cut index finger of a no. 7 surgical glove has been tied [72]. This finger balloon is sequentially filled with saline to the desired volume of 500 mL or less to facilitate dissection. Pressure–volume laboratory studies demonstrated similar intraballoon pressures between the index finger of a no. 7 and the middle finger of a no. 8 surgical glove after inflating with 500 mL saline [72]. No ruptures were noted *in vitro*. During clinical cases, a total of 38 patient procedures were performed using this method and finger balloon rupture occurred in three; all had undergone prior retroperitoneal surgery [72]. In one patient, all of the fragments could not be retrieved; however, no complications resulted during 6 months of follow-up.

McDougall *et al.* advocate use of the middle finger of a no. 8 Triflex surgical glove (Baxter Healthcare Corporation, Valencia, CA, USA), for which laboratory tests demonstrated that balloon pressures never exceeded 20 mmHg during filling to 2000 mL and the burst point was approximately 4000 mL [107]. They reported the use of their finger balloon in 12 retroperitoneal renal procedures during which they inflated it with 1000 mL of saline and experienced no balloon ruptures.

The initial port can also be inserted at the retroperitoneal entry site and the CO_2 insufflation begun at 15 mmHg pressure while the laparoscope is used to push into and sweep down the attachments between the posterior surface of Gerota's fascia and the psoas muscle [109]. These latter two methods do not, however, provide the same degree of anteromedial displacement of the kidney within Gerota's fascia that is so critical for rapid identification and access to the hilar structures.

A blunt-tip Hasson cannula may be utilized as the primary port at the initial entry site for insertion of the laparoscope. The fascial tacking sutures are wrapped around the guides on the inverted conical sleeve of the Hasson cannula, which is then seated down into the incision prior to locking it on the port sleeve to help prevent leakage of the pneumo-retroperitoneum. Other authors favor use of the Origin 10/12-mm blunt-tip cannula (Origin Medsystems, Santa Clara, CA, USA) at the initial entry site, as the internal retention balloon snugs tight against the inner aspect of the abdominal wall by sliding down the adjustable external cuff, creating an excellent seal resistant to leakage of CO_2 [109]. The retroperitoneum is insufflated to 15 mmHg pressure and the 10-mm 30° laparoscope is inserted.

Step 2: Identification of anatomic landmarks and secondary port placement

In a review of visualized anatomic landmarks following initial retroperitoneal access in 18 patients at the Cleveland Clinic, Sung *et al.* reported visualizing the psoas muscle (100%), lateral peritoneal reflection (83%), ureter (61%), renal artery pulsations (56%), aortic pulsations (90% on the left) and IVC (25% on the right) [110]. Due to the proximity of the port site placement during retroperitoneal procedures (6–8 cm) [70], it is often difficult to adequately visualize the site of port entry when introducing additional trocars, even with the 30º lens.

A reliable method of bimanual controlled introduction has been described [108]. In this method, the primary port is removed and the index finger of the nondominant hand is inserted and used to ensure that the peritoneal envelope is swept away as two ports are introduced at the mid-axillary line, one approximately two finger-breadths above the iliac crest and one just off the tip of the 11th rib (Figure 81.12). Placement of the lower mid-axillary port too close to the edge of the iliac wing will result in frustrating limitations of instrument excursion by the bone. The inserted finger can be protected using an S-retractor as described by Gill [70], which is especially important if bladed trocars are used. The use of fascial splitting trocars reduces the risk when performing this maneuver. A third trocar is then inserted just lateral to the palpated edge of the psoas muscle. The size of the inserted ports depends upon the dominant hand of the primary surgeon and the side on which the operation is being performed (Figure 81.12).

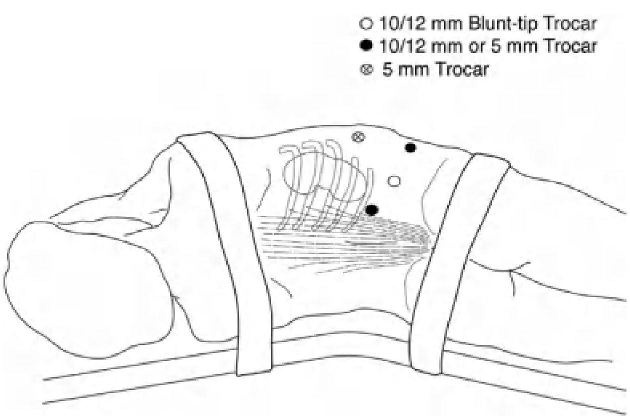

Figure 81.12 Typical trocar arrangement for a retroperitoneal renal procedure. The initial port is a blunt-tip Hasson-type inserted several finger-breadths below the tip of the 12th rib. Once the retroperitoneal space has been created and the peritoneal envelope swept medially, an additional port is inserted several finger-breadths below the 12th rib just lateral to the paraspinal muscles and slightly below the blunt-tipped port in the posterior axillary line. For right-sided procedures, this is a 5-mm port for a right-handed surgeon and a 10/12-mm port for a left-handed surgeon. For left-sided procedures, this is a 10/12-mm port for a right-handed surgeon and a 5-mm port for a left-handed surgeon. A 5-mm port is inserted just off the tip of the 11th rib in the mid-axillary line. A fourth port is inserted two finger-breadths (~3 cm) above the iliac wing in the mid-axillary line. For right-sided procedures, this is a 10/12-mm port for a right-handed surgeon and a 5-mm port for a left-handed surgeon. For left-sided procedures, this is a 5-mm port for a right-handed surgeon and a 10/12-mm port for a left-handed surgeon.

Step 3: Incision of Gerota's fascia and identification of hilar vessels

The laparoscope is inserted through the trocar located just off of the tip of the 12th rib and the surgeon works through the lower mid-axillary and posterior ports. The assistant retracts the kidney anterolaterally through the upper mid-axillary port to place the hilum on stretch (Figure 81.12). A longitudinal incision is made through Gerota's fascia and the psoas muscle is traced cephalad until the vigorous pulsations of the renal artery are visible beneath their fibrofatty, lymphatic covering. Early posterior identification of the artery is one of the primary advantages of the retroperitoneal approach. Once the artery is identified, the Harmonic scalpel is utilized to gently tease and divide the overlying fibrofatty tissue until the wall of the artery is encountered. The artery is then dissected circumferentially at the surface of its muscular coat until a right-angled or Maryland dissector can be readily passed behind it and spread to provide adequate space to secure and divide the vessel.

Step 4: Securing of hilar vessels

As described previously for the transperitoneal approach, options for securing the main renal artery include the 2.5-mm Endo-GIA stapler or self-locking Weck clips. As always, care must be exercised to be certain the tips of the stapler are visualized, as inadvertent clamping of cephalad and medial tissue on the right can result in partial transection of the IVC, and on the left the superior mesenteric artery can be injured.

Once the artery has been divided, the kidney should become noticeably less tense and the more anteriorly located main renal vein can be visualized. On the left side it may be necessary to circumferentially dissect, clip, and divide the adrenal, gonadal, and/or lumbar vein branches to allow adequate dissection and mobilization of the main renal vein for application of the Endo-GIA stapler. The vein should appear collapsed and the kidney decompressed; if it does not, a thorough

inspection caudal and cephalad to the main renal artery should be performed to ensure that no accessory arteries are present. If accessory arteries are identified, these must be secured and transected prior to stapling the main renal vein to prevent engorgement and vigorous bleeding from the kidney and vein stump. Once the collapsed main renal vein has been adequately mobilized, the 2.5-mm Endo-GIA stapler is utilized to secure and divide it. Again, it is critical to observe the entire length of the stapling device to prevent accidental injury of anteromedial structures.

Step 5: Transection of ureter and release of inferior attachments

The fibrofatty tissues above and below the transected hilar vessels are teased away with the Harmonic scalpel. The ureter and gonadal vein, if its entry point remains with the specimen, are identified medially on the psoas, dissected circumferentially, clipped, and divided. At this point the ureter can be grasped and retracted laterally, while the entire lower pole is freed of all its attachments using the Harmonic scalpel.

Step 6: Release of cephalad attachments and adrenal gland

Downward traction on the ureter helps to expose the upper pole of the kidney, which is then separated from the adrenal gland by inserting the jaws of the Harmonic scalpel along the juncture of the two, allowing time for adequate hemostasis. The ureter is alternately held lateral and medial while applying downward retraction as indicated to provide adequate exposure of the dissection plane. Once the adrenal gland is released, no significant attachments to the kidney should remain and it can be moved freely in the retroperitoneum.

Step 7: Entrapment with morcellation or intact removal of the specimen

Once the specimen is free within the retroperitoneum it can be placed in an entrapment sac and either delivered intact by enlarging the primary or lower mid-axillary port [70] or it can be morcellated as described for transperitoneal procedures. Use of the LapSac is cumbersome given the confines of the retroperitoneal space, but it can be introduced via the 10/12-mm port site and positioned with the closed end directed deep into the pelvic extent of the extraperitoneal space while the kidney is kept high in the retroperitoneum. The ureter and lower pole are gently swept into the bag in a longitudinal orientation as the surgeon holds two of the tabs on the mouth of the bag to keep it open as the kidney is delivered inside. As discussed for the transperitoneal approach, the advantage of using this bag for removal of benign specimens include its resistance to mechanical perforation and lack of permeability to uropathogens when morcellating infected specimens [96, 97]. Gill describes the use of one of the ring-mounted entrapment sacs (e.g. EndoCatch I or II), which can be inserted at one of the 10/12-mm port sites, the specimen entrapped, and the port site enlarged to allow intact removal [110]. If the port site is enlarged to deliver the specimen intact, the fascial incision is then closed using a running #1 Polydioxanone suture.

Step 8: Exiting the retroperitoneum and port closure

The pneumo-retroperitoneum is lowered and the areas of dissection are once again inspected under both high (15 mmHg) and low (5 mmHg) insufflation pressures. Once hemostasis is felt to be adequate, the pneumo-retroperitoneum is evacuated, the ports are removed, and the S-retractors are utilized to put a simple fascial closure stitch at the remaining 10/12-mm port site. Since the peritoneum is not violated, full-thickness closure utilizing a device such as the Carter–Thomason is not required and is often difficult to use due to the proximity of the ports. The remainder of the skin closure and dressings is as described for transperitoneal nephrectomy.

Postoperative care

The patient is usually encouraged to begin ambulation or to at least sit up in a chair on the night of their surgery. That night, or the following day, clear liquids are initiated if bowel sounds are present and the patient is ambulated at least per shift. Pain is controlled with the use of parenteral agents or a patient-controlled analgesia device. We maintain compression devices and Ted Hose while the patient is at rest in bed or sitting in a chair. The orogastric tube is removed immediately following the operation and the Foley catheter is typically removed once the patient is ambulating on postoperative day 1. If the patient has a history of voiding abnormalities, we often wait to remove the Foley catheter until the second postoperative day. Broad-spectrum antibiotic coverage is continued for 24 h following surgery and is converted to a week-long course of an oral agent appropriate for the patient's situation should a suspected infection exist. We typically use a sulfa-based agent or a fluoroquinolone. If clear liquids are tolerated without bloating and active bowel sounds are present, the patient's diet is advanced to general on postoperative day 2, and they are switched to oral pain medication. Once the patient is tolerating a regular diet, their pain is well-controlled on oral agents, and they are

passing flatus, they are discharged from the hospital. Typically, discharge occurs on postoperative day 2 or 3, and is most commonly delayed by slow return of bowel function. If active flatus is not occurring by day 2, we help stimulate its return by administering a bisacodyl suppository.

Results

Laparoscopy for benign disease is being offered at many academic centers, as well as community-based hospitals. The results of several larger series of laparoscopic simple transperitoneal and retroperitoneal nephrectomy are summarized in Tables 81.4 and 81.5. Operative times typically average 2.5 h [111], although mean reported times of 7 h demonstrate the potential complexity of these dissections [113]. A five-fold reduction in the amount of narcotic analgesia relative to open nephrectomy, as demonstrated by McDougall and Clayman [120], with convalescence times of 2–4 weeks reflect the benefits of laparoscopy. Mean length of stay in most reported series still averages slightly more than 3 days [113], and slightly longer in European and Asian series, which in large part may be a reflection of differing criterion for discharge [114].

A review by Landman *et al.* of three comparative series (one European) totaling 67 laparoscopic simple (50 transperitoneal; 17 retroperitoneal) versus 55 retroperitoneal open nephrectomies for benign disease demonstrated mean operative times of 241 and 146 min, respectively [121]. Length of stay and time to full recovery averaged 5.1 and 30.8 days for the laparoscopic group and 8.5 and 145 days for the open group, respectively. Open conversion was required in five (7.5%) of the 67 patients, which is similar to the 8% open conversion rate in 106 transperitoneal laparoscopic simple nephrectomies reported by Eraky *et al.* [2]. As stated earlier, many simple nephrectomies are far from simple due to the scarring associated with the pathologic process. Indeed, the underlying renal pathology has been shown to have a direct correlation to the incidence of conversion, with renal tuberculosis, post-traumatic renal atrophy, infarcted kidneys, and xanthogranulomatous pyelonephritis having an open conversion rate of 89% in one large multi-institutional German study [122].

Eraky *et al.* reported one of the largest single institution experiences with transperitoneal laparoscopic simple nephrectomy (Table 81.4) [2]. These authors performed a total of 106 laparoscopic transperitoneal nephrectomies for primary indications consisting of chronic pain, recurrent infection, or associated hypertension. The open conversion rate in their series was 8%, with five cases due to failure to progress secondary to adhesions, three due to bleeding, and one due to inability to entrap the specimen. All specimens were entrapped and manually morcellated in a LapSac. Mean operative time was 186 min overall, but averaged 217 min for the initial half of the series and 154 min for the latter half. There were four major complications, including a pulmonary embolism, colonic perforation requiring colostomy, and an infected hematoma requiring percutaneous drainage. The mean hospital stay was 2.9 days.

Hemal *et al.* reported one of the largest single-institution experiences with retroperitoneal laparoscopic simple nephrectomy (Table 81.5) [1]. These authors performed a total of 185 laparoscopic retroperitoneal nephrectomies or nephroureterectomies for benign conditions, including 154 nephrectomies for such indications as UPJO (77), stone disease (53), ureteral stricture (9), tuberculosis (7), dysplasia (4), ectopic ureterocele (2), and renovascular hypertension (2). A total of 18 patients required conversion to open surgery (9.72%) with 14 of these conversions occurring during the first 100 cases. Four conversions were urgent (three for bleeding; one for colon injury) and 14 were elective due to failure to progress as a result of adhesions (12) or loss of the pneumo-retroperitoneum secondary to a peritoneal rent (2). The average operative time for completed laparoscopic procedures was 100 min and the mean blood loss was 133 mL. Four patients required a blood transfusion. Seven major complications (3.78%) were reported, including the four which led to an open conversion and a retroperitoneal collection requiring exploration and drainage. Thirty-two minor complications (16.2%) occurred, including the two peritoneal violations that led to open conversion [1].

Fornara *et al*. reported their series of 11 kidney transplant patients who underwent bilateral laparoscopic transperitoneal native nephrectomies [68]. Mean operative time was 195 min and blood loss was 345 mL. One patient required open conversion due to bleeding from the renal artery. Complications included a retroperitoneal hematoma requiring a 2-unit blood transfusion, fever of unclear etiology, and a urinary tract infection. Postoperative renal function was stable in all patients and the mean analgesia requirement was 14 mg morphine equivalent and hospital stay 4.2 days. This compared favorably to 10 patients at the same institution who had bilateral open nephrectomies. The open surgery group required three times the amount of postoperative analgesia and had a mean hospital stay of 10.7 days [68].

As mentioned previously, two infectious conditions of the kidney for which the laparoscopic approach has demonstrated questionable results include xanthogranulomatous pyelonephritis (XGP) and renal tuberculosis. XGP is an intense infectious/inflammatory condition of the kidney associated with chronic infection, obstruction, and the presence of renal calculi. CT scan imaging

Table 81.4 Results of laparoscopic simple nephrectomy: transperitoneal.

Series	Number	Operative time (mean, min)	EBL (mean, mL)	Open conversions	Extraction method(s)	Analgesia (morphine equiv, mg)	Complications (minor)	Complications (major)	LOS (mean, days)	Convalescence (mean, days)

usually demonstrates enlargement of the kidney with a "bear-paw" appearance resulting from fat-laden macrophage replacement of the collecting system (see Figure 81.1). The disease results in an intense fibrotic response around the kidney with adhesion to adjacent structures, including bowel, adrenal gland, liver, IVC, aorta, spleen, pancreas, and psoas muscle. Fistula formation to the colon or skin of the flank has been reported [123, 124]. A review by Bercowsky *et al.* demonstrated a 60% complication rate in five patients undergoing laparoscopic removal, with a mean operative time of 6 h, bringing into question the utility of laparoscopy in this setting [125].

Reported open conversion rates for attempted laparoscopic nephrectomy for renal tuberculosis are as high as 80% in the most experienced hands [122], with spillage of caseating material reported by several groups [126, 127]. The need for extended multidrug therapy following this type of occurrence and the difficulty of these operations makes this another questionable disease for which laparoscopic nephrectomy should be utilized.

ADPKD represents a challenging condition due to the size of the kidneys, with many extending across the midline or deep into the pelvis [27, 128]. The significant size of these specimens requires initial cyst decompression utilizing the Harmonic shears, with irrigation and aspiration of the released fluid to allow adequate exposure of the hilum for dissection [129]. A comparison of 10 ADPKD kidneys removed laparoscopically compared to 10 removed with the open procedure demonstrated no complications in the laparoscopic group with a significant reduction in hospital stay (2.6 versus 6.6 days, respectively) [130]. Mean laparoscopic times were, however, significantly longer than in the open group (247 vs 205 min) with one case converted to an open procedure.

Complications

The reported complications with establishment of transperitoneal and retroperitoneal access for any laparoscopic approach can also occur during laparoscopic simple nephrectomy. In a review of 2407 laparoscopic cases in urology, Fahlenkamp *et al.* demonstrated a 0.2% incidence of adjacent organ perforation [131]. This is similar to the 0.3% rate access-related injuries reported during gynecologic surgery [132, 133]. The use of an open blunt-tip trocar access as described by Hasson [134] is not a guarantee against injury. Penfield reported a 0.06% bowel injury rate using an open access technique in 10 840 laparoscopic cases [135]. Two aortic injuries have also been reported using the Hasson technique [136].

Several reviews have specifically assessed the complications inherent to nephrectomy and stratified them relative to the type of nephrectomy performed [63, 122, 137]. Siquiera *et al*. described their experience with 213 laparoscopic nephrectomies, which included 84 live donor nephrectomies, 61 radical nephrectomies, 55 simple nephrectomies, and 13 nephroureterectomies. The majority (196) were performed via a transperitoneal approach with the exception of 17 retroperitoneal simple nephrectomies. A total of 16 major (7.5%) complications occurred, which included three (1.4%) that were access-related, nine (4.2%) intraoperative, and four (1.9%) postoperative complications. Only one complication, a liver laceration on initial trocar insertion, occurred in the group undergoing a laparoscopic simple nephrectomy, but this group had the highest rate of elective conversion (12.7%) due to lack of progression (seven of the eight elective conversions).
